Faithful Sampling

We now try out a slightly different kind of sampling, which we hope we ameliorate some of the problems that we have encountered with flat top sampling. Now, this is normal clature that is I think you need to me, but I like to call this faithful top sampling.

(Refer Slide Time: 00:41)

Let me demonstrate with the figure, let $x(t)$ be as usual something of that shape, this is $x(t)$. Now, we want to have a sample train that consists of non ideal pulses that is to say rectangular pulses, but these pulses will be exactly equal to the values of $x(t)$ at the points where they occur, that we show what that means? That was one pulse, second pulse and so on, essentially it is like this. This I will call $x(t)$ of t , $x(t)$ of t equals $x(t)$ when $t \bmod T_s$ is less than T_s and it equals 0 when $t \bmod T_s$ is greater than T_s , fine.

So, this is the definition of the faithful top sampled sequence, simple top sample train, faithful top sampled train, the rectangular sampling technique that we discussed before was called flat top sampling. There it was flat at the tops of the samples of the sample pulses. Now, it follows the contour of the signal, this might seem like a minor difference,

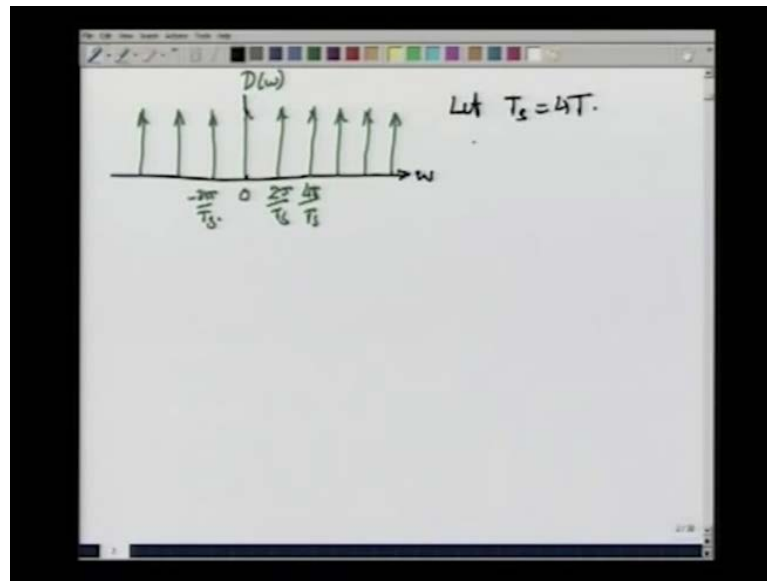

but it turns out that it makes a considerable impact on the spectrum of the sampled signal. Now, the first question we have to ask ourselves is, how do we construct this faithful top sampled signal.

Now, for the rectangular sample case for the flat top sampled case, what we did was we constructed the ideal impulse train first $x_s(t)$, and then convolved it with a rectangular pulse since it was a non causal rectangular pulse, each impulse was replaced by a rectangular pulse of width $2t$. Therefore, it was flat at the tops, this is what we did? Now, we had to have something that slightly different. What we do is we take a rectangular pulse train. This is rectangular pulse as we know is $R_T(t)$, which is equal to 1, if $\text{mod } t$ is less than t and equal to 0. If $\text{mod } t$ is greater than equal to t , this is the rectangular pulse.

Now, we want to have a train of such pulses that is to say, we will construct a function, which is summation over all $n R_T(t - nT)$. This we shall call say p_t , we shall call it p_t . It is rectangular pulse train, finally we can show that the faithful top sampled sequence sampled train. $x_s(t)$ is given by $x(t)$ multiplied by p_t . This is the way we can mathematically express the form of $x_s(t)$, but then how we do go about generating this? [FL] So, the first step is to get p_t , which is a periodic repetition of a fundamental rectangular pulse $R_T(t)$. Now, how is that achieved? Well, we take the original impulse train, which is D_t and simply convolved with $R_T(t)$.

So, p_t equals $R_T(t)$ convolved with D_t , which means of course, that $p_t(\omega)$ will be equal to $R_T(\omega)$ multiplied by $d(\omega)$. Now, let us go back and recall for the n times what is $d(\omega)$ $d(\omega)$ was 2π by t summation over $k \delta(\omega - k \frac{2\pi}{t})$. This was $d(\omega)$ $R_T(\omega)$ was given by $2 \text{ times } \sin \omega t$ by ω , right? So, we now have both of these and we have to multiply them. So, let us sketch each of these functions and see what that product begins to look like first of all $d(\omega)$.

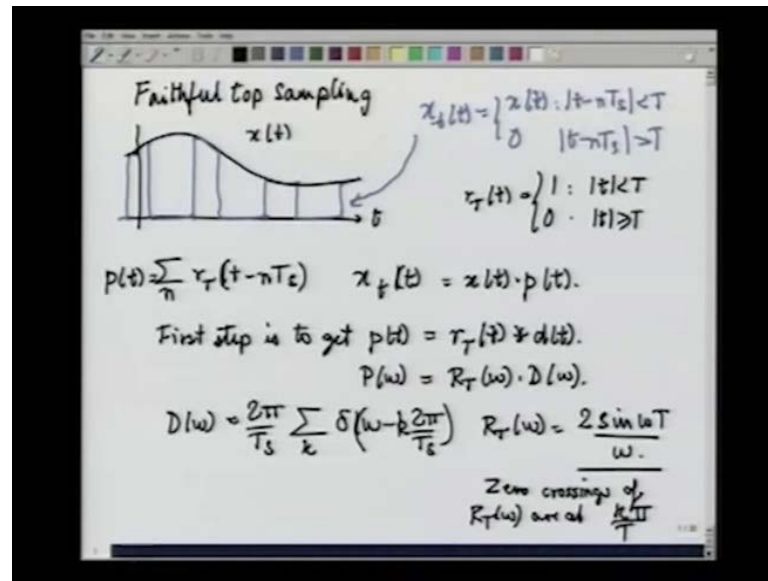

(Refer Slide Time: 09:00)

Now, the impulses that are components of $D(\omega)$ are placed $1/T_s$ or rather $2\pi/T_s$ apart from each other. Since, T_s is believed to be considerably larger than T , which is the width of the modulating pulse, it follows that $1/T_s$ will be much smaller. Hence, we expect $2\pi/T_s$ spaced pulses to be much closer to each other than $2\pi/T$. So, let us first make this the ω axis this is all the frequency domain in which things are happening. Let us first make a plot of these functions, so if this is ω equal to 0, this is at $2\pi/T_s$, $4\pi/T_s$ minus $2\pi/T_s$ and so on.

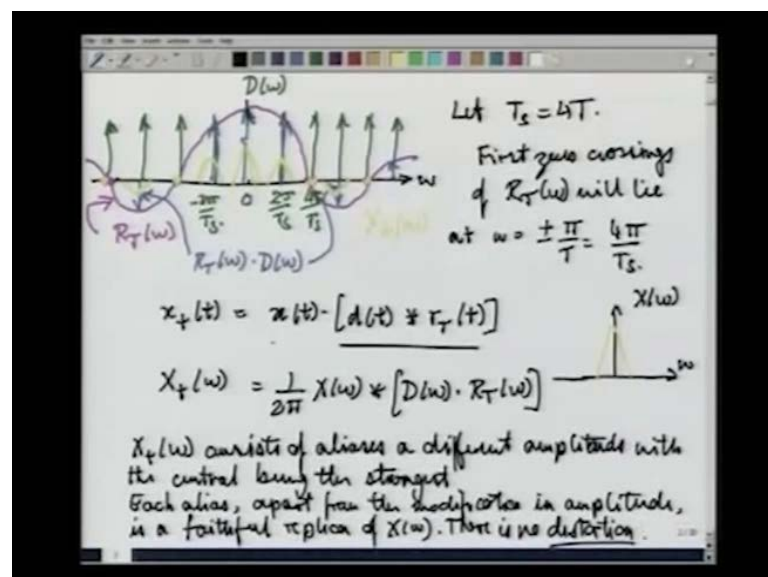

We said these frequencies that these frequency domain impulses related to $d(\omega)$ of t , $d(\omega)$ are present. Now, let us say that capital T , which is the width of the rectangular pulse, is one-fourth of capital T_s . So, let T_s be equal to say $4T$ that is just a matter of convenience it often could be higher. Now, if T_s is $4T$, now let us go back to the equation for $R(T)f(\omega)$.

(Refer Slide Time: 11:37)

Now, $R_T(\omega)$ is equal to $2 \sin \omega T$ by ω where are the minima where are the not minima about the 0 crossings of this function the first 0 crossing. There is no 0 crossing at ωt equal to 0. The first 0 crossing is observed at ωt equal to π and minus π the left and right respectively right and left respectively. So, when ωt equals π you find that ω must be equal to π by t right next when ωt equals 2π . You again get 0 crossing, so ω then ω equals 2 times π by t and so on. Essentially then the minima the 0 crossing sorry of $R_T(\omega)$ at plus or minus $k\pi$ by t plus or minus $k\pi$ by t . We can just say $k\pi$ by t or $k\pi$ by t , alright?

(Refer Slide Time: 13:29)

Now, since t_s is 4 times t , we find that the first place the first 0 crossing on the same coordinate same will be found at the place where you can find π by t . So, the first this is a sin function, which will 0 crossings and the first 0 crossings of $R T$ of ω will lie at ω equals plus or minus π by t , which is equal to, since t is equal to t_s by 4, you get four π by t_s . So, let us see where is 4π by t_s , this is the place and let us now use a different colour say this, so this is the first 0 crossing of π by t . Similarly, on this side this is the first 0 crossing of π by t . This place now between these two places you have the curve of $R T$ of ω which is a sin function. So, it will be a function that goes like this.

Then the next 0 crossing will be at 8π by t_s . That will be here and here, if it one more, so this is the next place where you will find the 0 crossing of this function. So, you will get something like that goes like this and here too you will get something that goes like this and then goes on like this goes on like this. So, that is the layout of this new function which is $R T$ of ω this is $R T$ of ω . Now, remember we now convolve this two functions, we multiply them, and when we multiply them all that happens is that the impulses in $b \omega$ get appropriately modified in amplitude by the amount of the value of $R T$ of ω at the at that respective place.

So, you get new vectors, we will just draw them over here in say blue you have this. Then you have 0 at this place and this place when you have and so on. So, the blue function is actually $R T$ of ω multiplied with D of ω . This is what we have just drawn have also this. For example, and all the other impulses of various heights in the train, so this is $D \omega$ times $R T$ of ω . Now, what do we do finally with this? Let us get back to original equation, we have for faithful flat top sampling a multiplication of $x t$ that is $x t$ of t the faithful top sample sampled train was equal to $x t$ multiplied by D of t convolved with $R T$ of t .

Now, that we have evaluated the transform of this we just have to see what to do about the multiplication well using the modulation property. That is stated as follow we find that $x t$ of ω equals 1 by 2π $x \omega$ convolved with this function $D \omega$ multiplied by $R T$ of ω $D \omega$ multiplied by $R T$ of ω is already here in terms of in the form of these blue impulses. This has to be convolved with $x \omega$. That means at each place where you have an impulse of $D \omega$ multiplied by $R T$ of ω you create a copy of $x \omega$. A shifted copy of $x \omega$, which is also scaled by the

appropriate value of the height of the pulse $d\omega_r t\omega$, thus for example, if let us say we plot $x\omega$ over here against ω .

We get a function that looks like this. Let us say $x\omega$ is like this, so this is minus b and this is b . Suppose, this what we had, then you will find over here at all areas. Let me just change the colour, I think it does not look appropriate. It is confusing us with something else. Let me choose different colour for this, let me draw it out of yellow here. I hope everybody can see this yellow colour, but it is there is an yellow pulse over there. Now, we want to make yellow triangular pulses at each pulse, but the height of the pulses will be different depending upon the height of the local impulse of $D\omega$ times $R T\omega$.

Since, each of this is of different height we will get one impulse like this one pulse one copy like this, another slightly shorter over here, over here. Then there is 0 over these two places. Then there is a negative pulses like this over here and here and then again the 0 over here and over here. So, this is what we are getting we are getting we observe the following well what we have just plotted in yellow is $x t$ of ω $x t$ of ω is the final spectrum of the faithful top sampled sampled train. Thus the spectrum of that now what can we say about $x t$ of ω $x t$ of ω consists of aliases of different amplitudes with this the central areas being the strongest, the central areas being the strongest.

A more important observation than this is the following each areas apart from the modification in amplitude is a faithful replica of $x\omega$. There is no distortion. We should put this in capital letters, there is no distortion. If I may say more pointedly there is no distortion unlike in the flat top sampling case. There is no distortion in the faithful top sampling case.

So, faithful top sampling has solved the problem of distortion. If we can have an ideal low pass filter to retrieve only the central areas and reject the others. Then we have assuming of course, we have followed the sampling theorem, we have exactly what we want we have the central areas taken out. So, you get a copy of the original function, fine? So, let us write out the expression for $x t$ of ω .

(Refer Slide Time: 25:59)

$$X_T(\omega) = \frac{1}{2\pi} \cdot \frac{2\pi}{T_s} \sum_k \frac{2 \sin \omega T}{\omega} X\left(\omega - \frac{2\pi k}{T_s}\right)$$

$$R_T(\omega) \cdot D(\omega) = \frac{2\pi}{T_s} \sum_k \frac{2 \sin \omega T}{\omega} \delta\left(\omega - \frac{2\pi k}{T_s}\right)$$

$$X_T(\omega) = \frac{1}{T_s} \sum_k \frac{2 \sin \omega T}{\omega} X\left(\omega - \frac{2\pi k}{T_s}\right)$$

By lowpass filtering with $L(\omega) = \begin{cases} T_s & |\omega| < B \\ 0 & |\omega| \geq B \end{cases}$

$$X_T(\omega) \cdot L(\omega) = \underline{2X(\omega)}$$

Faithful top sampling followed by ideal lowpass filtering will yield an undistorted output $= 2X(\omega)$

$X_T(\omega)$ equals $\frac{1}{2\pi}$ times the convolution of $X(\omega)$ with the impulse train that was the modified impulse train $R_T(\omega) \cdot D(\omega)$. Now, $R_T(\omega) \cdot D(\omega)$ will essentially be equal to... First of all, let us write that expression $R_T(\omega) \cdot D(\omega)$ is equal to summation over all k to sine ωT by ω multiplied by $\delta(\omega - \frac{2\pi k}{T_s})$. This is $R_T(\omega) \cdot D(\omega)$ per times $D(\omega)$. This is an impulse train of varying heights and this is now convolved with $X(\omega)$ to get $X_T(\omega)$.

So, $X_T(\omega)$ is $\frac{1}{2\pi}$ and we missed something over here. I think we have this is actually $\frac{2\pi}{T_s} \cdot D(\omega)$ also has a multiplying factor of 2π by T_s outside. So, you have this as $R_T(\omega) \cdot D(\omega)$. Now, we have over here $X_T(\omega)$ given by $\frac{1}{2\pi}$ convolved with this. That means at every pulse over here at every impulse over here. We replace $X(\omega - \frac{2\pi k}{T_s})$ by $X(\omega)$. So, you get this times 2π by T_s summation over all k of $2 \sin \omega T$ by ω times $X(\omega - \frac{2\pi k}{T_s})$. This is the expression where of course, 2π may be cancelled. So, that we finally get $X_T(\omega)$ equals $\frac{1}{T_s}$.

Summation over all k $2 \sin \omega T$ by ω multiplied by $X(\omega - \frac{2\pi k}{T_s})$. Now, this gives all the aliases of $X_T(\omega)$, but we in the process of reconstruction or retrieval will get rid of all except the central areas. So, we will apply the following by low pass filtering with $L(\omega)$ given by $L(\omega) = T_s$.

For mod omega less than b equal to 0, for mod omega greater than equal to b what do we get? We get x t omega multiplied by 1 omega and when you do the multiplication you find that every areas other than this central areas is out of the picture. So, you simply get now with t s cancelling the t s.

In the denominator in x t of omega, you just get x. Let us see sine omega t by omega evaluated at omega equal to 0 will give you 1. So, you will have 2 x omega, that is at you practically got what we wanted except for this scale factor to which cannot just be adjusted. So, faithful top sampling is capable of undistorted retrieval faithful top sampling, followed by ideal low pass filtering ideal low pass filtering will yield an undistorted output equal to 2 x omega.

SIGNALS & SYSTEMS

FAITHFUL TOP SAMPLING

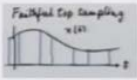

- Pulses resulting from faithful-top sampling will follow exactly the values of the input signal during the ON time of each pulse in the train.
- Mathematically, a multiplication of the input signal with a rectangular pulse train is carried out, with the rectangular pulse train viewed as a convolution of a single rectangular pulse with an ideal unit impulse train.
- Faithful top sampled train: $X_s(t) = x(t) \cdot p(t)$
- Rectangular pulse train: $p(t) = \sum_n \tau_T(t - nT_s)$

$$X_s(t) = x(t) \cdot p(t) = \sum_n x(t) \cdot \tau_T(t - nT_s)$$

$$X_s(\omega) = \mathcal{F}[x(t) \cdot p(t)] = \frac{1}{2\pi} [X(\omega) * P(\omega)]$$

$$P(\omega) = \frac{2\pi}{T_s} \sum_k \frac{2 \sin \omega T}{\omega} \delta\left(\omega - k \frac{2\pi}{T_s}\right)$$

$$X_s(\omega) = \frac{1}{T_s} \sum_k \frac{2 \sin \omega T}{\omega} X(\omega - k \omega_s) \quad : \quad \omega_s = \frac{2\pi}{T_s}$$
