Lecture - 40
Laplace Transform

We are now going to start discussion on an entirely a new topic; and this will be called Laplace transform.

(Refer Slide Time: 00:30)

Having studied so many transforms already one might wonder why we need to look at one more transform. Now, this transform is for continuous functions, continuous time and in certain way can be understood as a sort of generalisation of the continuous time Fourier transform. Both, I mean the continuous Fourier transform attempted to represent both periodic and non periodic continuous time functions using representing signals, which were only periodic complex exponentials. So, the representing signals are always periodic complex exponentials in the CTFT case.

We know that the general complex exponential given by $X(t) = e^{(\sigma + j\omega)t}$, where the parameter of the exponential is a complex number is also preserved a preserved signal under the linear time invariant processing. But so far we have not given any opportunity for a real component of the exponential to play any useful role, this is what we are now going to do. Now, so one way of looking at the

Laplace transform is that. It is a generalisation of the Fourier transform in which the frequency is allowed to be complex.

Earlier it was allowed to be only imaginary that is to say we had only $j\omega$ as exponent. Now, we are allowing $\sigma + j\omega$, so that is one way of giving the Laplace transform as the generalisation of full wave transform. But more importantly we know that the full wave transform had certain limitation the full wave transform existed only for signals which are absolutely intergrable or summable, integrable. So, the full wave transform existed only if this was true, so if the absolute integrability was not assured then probably the Fourier transform would not convert, this is what we were faced with.

What we are now going to do is, to see is by modifying extreme some manner we can make an extreme, which was inherently unable to meet this criteria into one which can meet this criteria. This is the second way of looking at in the Laplace transform as the means of generating a Fourier transform of a modified signal and studying at four different levels or different degrees of modification. So, modify time signals $X(t)$ and study the existence of its of the modified signals continuous time Fourier transform for different degrees of modification extends of modification, so let us give the definition the Laplace transform of $X(t)$ is written as $X(s)$.

(Refer Slide Time: 06:04)

$$X(s) = \int_{-\infty}^{\infty} x(t) e^{-st} dt \text{ where } s = \sigma + j\omega$$
 Thus X is actually dependent on 2 quantities σ and ω . Thus, $X(s)$ requires 2-dimensions for the indep variable. Thus, we require to make 2 3-D plots - a real pt. 3-D plot $\text{Re}[X(s)]$ vs σ, ω , and $\text{Im}[X(s)]$ vs σ, ω .

$$X(s) = X(\sigma + j\omega) = \int_{-\infty}^{\infty} x(t) e^{-\sigma t} e^{-j\omega t} dt.$$
 this is the FT of $x(t) e^{-\sigma t}$.

It is defined as $\int_{-\infty}^{\infty} x(t) e^{-st} dt$ where s equals $\sigma + j\omega$. So, what we get in the transform domain is a function of a complex variable earlier we had only a function of an imaginary variable. If we looked at $j\omega$ or a real variable, if we look at only ω , but being s now being a complex number there are two variables, which can change the dependent σ and ω thus X capital X is actually dependent on two quantities σ and ω . This means something drastically new has happened, we can no longer really plot the Laplace transform of a function $x(t)$ like we plotted the Fourier transform spectrum of the same function, because now it depends on two variables.

So, now what we have is a plot of two independent variable a plot that depends on two independent variables it is what we call a 3 D plot thus $x(s)$ requires two dimensions for the independent variable further more $x(s)$ itself can be complex. So, at each point s equal to $\sigma + j\omega$ $x(s)$ will have a real part and an imaginary part or a magnitude part and a phase part. Hence, you would actually get two 3 D plots the real 3 D plot plus the imaginary 3 D plot or the magnitude 3 D plot plus the phase 3 D plot.

Thus we required to make two 3 D plots a real part 3 D plot real $x(s)$ verses σ and ω and imaginary $x(s)$ verses σ and ω . So, this gives us the picture of what we expect with this introduction to the Laplace transform. Let us now see, what we can say about it next this much is about the Laplace transform we see if we write the expression for as we have done just now and try to interpret as the Fourier transform. What actually happens? $X(s)$ equals $X(\sigma + j\omega)$ and this equals the integral minus infinity to infinity.

$x(t) e^{-st}$ is actually $e^{-\sigma t} e^{-j\omega t}$, which can we looked upon as the Fourier transform of this function. That is this is the Fourier transform of $x(t) e^{-\sigma t}$. While this just seems like a interpretation this will form the basis of our perception of the Laplace transform throughout the discussion this will be the most convenient and easy way of trying to understand the Laplace transform. So, I will start the rest of the discussion by prefacing it with the brief review of how $e^{-\sigma t}$ behaves for different values of σ .

(Refer Slide Time: 11:28)

Let us make a plot one point is sure e to the minus is greater than 0 for all t and all σ this is a point s where the observing thus the absolute integrability of e to the minus σt is the same as the integral integrability of e to the minus σt . Now, let us make some value make some plot for different values of σ let us take this point as 1. Now, suppose σ is greater than 0, if σ is greater than 0 and you plot e to the minus σt for positive time we know that it is a decaying exponential, which means for negative time it is a growing up or growing exponential.

So, we can make a plot that goes like this is for some value of σ if you choose a smaller value of σ that is to say σ is greater than 0, anywhere. But we are saying choose a value of σ closer to 0 than this one then you will have a an exponential that is closer to flat that means you would have an positive time something like this. So, this we will call σ_2 this will call σ_1 then we will have σ_1 is greater than σ_2 this much we know.

Now, let us make another plot where σ is actually equal to 0 just a flat horizontal line that is given as thus equal to 1 for all time then suppose σ is less than 0, but small that is mod σ is small. But σ is negative then you will have a function e to the minus σt is raises for positive time and is decaying towards negative time. So, you get a curve that looks like this we call this σ_3 next if you make a large negative

when we are sigma that this sigma 4 less than sigma 3, then we will have something that rises faster in positive time and slower in negative time and falls faster in negative time.

So, we have so if this is sigma 4 then we know that sigma 3 is greater than sigma 3 is greater than sigma 4 we know this, so these are the various plots of $e^{-\sigma t}$ for different values of sigma. Now, the argument goes as follows suppose $x(t)$ is causal it means to say $x(t) = 0$ for $t < 0$ only towards the right. It has non 0 values towards the left of $x(t) = 0$ it has 0 values. Suppose that the $x(t)$ of x exists that is to say suppose that this is thus it is absolutely summable, absolutely integrable when it is absolutely integrable.

Then let us see what we can say about $e^{-\sigma t} x(t)$ if $e^{-\sigma t} x(t)$ is to be absolutely integrable, that means the product should have an area that does not grow up. Thus if we will have some value of sigma for which this is the case sigma 1 for which $x(t) e^{-\sigma t}$ sigma 1, t is integrable I mean of course is absolutely integrable. I think I will abbreviate this as I absolutely integrable we will say is I then it is evident that for any sigma to greater than sigma 1 the absolute integral of $x(t) e^{-\sigma t}$ minus sigma 2 t will be less than the absolute integral of $x(t) e^{-\sigma t}$ minus sigma 1 t correct.

Because this decays faster in positive time thus evident if you look at this pictures this function versus this function clearly that is this function is falling faster in positive time than this function. And $x(t)$ is causal when it falls faster the area under the product will be less than it was for case of sigma 2 except that here we have chosen sigma 2 greater than sigma 1 here we have chosen sigma 1 greater than sigma 2. So, let us not confuse this sigma 1 sigma 2 with this sigma 1 sigma 2.

(Refer Slide Time: 20:03)

Hence, If the L T of $x(t)$ exists it exists for σ_1 it will also exist for every σ_2 greater than σ_1 that is an interesting point to observe alright. So, this is the way we proceed we look at some function $x(t)$ and see if there is any σ for which $x(t)e^{-\sigma t}$ has a Fourier transform. If it has a Fourier transform then we will say that $x(t)$ has a Laplace transform for that value of σ , now the terminology terms out to be different in the case of the Fourier transform.

It was a do or die kind of situation either $x(t)$ has a Fourier transform or does not have a Fourier transform for the case we are continuing as time Fourier transform $x(t)$ either has a transform or it does not or it does it was just make or break black or white. Whereas, in the case of the L T it turns out that there can exist certain values of σ for which the L T exists other values of σ for which the L T does not exist. Thus how it is the set of points of σ for which the Laplace transform does exist is called its region of convergence it is called its region of convergence anyway we get R O C, all right?

So, this is where the Laplace transform fundamentally differ from the Fourier transform it has to make a record not just of what the Laplace transform of $x(t)$ is what value this, but also where those values are valid what points of s are those values are valid now. To make things more graphical and easy to picture we make what are called s plane plots s plane. Plots essentially are plots of the plane σ ω where σ is on the horizontal axis and ω is on the vertical axis and the s plane plot of array of $x(t)$

divides s planes into regions over which x s exists or fails to exist. So, in some regions x s will exist and in some regions x s will not exists may not converge. So, this is called an s plane plot example for x t equals e to the minus a t u t, which is just like the causal example we have just done through.

This is also a causal example then e to the minus a t is some kind of occur e to the minus a t is some kind of occur which depends on the value of a. So, thus the point plotting next curve what we will do instead is to understand its Laplace transform e to the power minus a t u t have a Laplace transform x of s equal to integral minus infinity to infinity e to the minus a t u t e to the power minus s t d t. That is equal to because there is u t to over there 0 to infinity e to the power minus a minus sigma minus j omega t d t. This can be rewritten as summation from 0 to infinity e to the power minus a plus s into t d t.

(Refer Slide Time: 26:16)

$$\frac{e^{-(a+s)t}}{-(a+s)} \Big|_0^\infty = \frac{1}{s+a}$$

Real factor of $e^{-(\sigma+a)t} = e^{-(\sigma+a)t} e^{-j\omega t}$
 $e^{-(a+s)t}$ must decay over positive time.
 $a + \sigma > 0$ or $\boxed{\sigma > -a}$ Region of Convergence
 $X(s) = \frac{1}{s+a}$

Let us assume that this integral converges if this integral converges then its integral will be e to the power minus a plus s times t divided by minus a plus s evaluated from 0 to infinity for t and this comes out to be equal to 1 by s plus a. But in order to assume that its convergence we have to see for what values of sigma this integral will actually converge. Now, the real part of into e power s plus a the real factor of e power minus s plus a times t is e power minus sigma plus a t e power minus j omega t this what we have.

Now, you see $e^{\sigma t} \cos \omega t$ is not integrable because both its real and imaginary parts have finite power and not finite energy where not integrable that is the end of $\cos \omega t$. So, any hope we may have of $x(s)$ existing will rest with whether this is a decaying exponential over the interval of integration that means $e^{\sigma t}$ must decay over positive time. So, that when multiplied by something like $e^{-j\omega t}$ which has finite power and not finite energy the product will still have finite power and will still be absolutely integrable.

Now, let us see what this means, this means that σ must be greater than 0 or that σ must be greater than $-\infty$, in fact σ must be greater than $-\infty$ it defines the so called region of convergence. This is the region of convergence of $x(s)$ given by $1/(s+1)$. So, this formula is valid only for this interval of s plane this part of the s plane thus it is clear that unlike the days of the continuous time Fourier transform where we nearly needed to take a record of the algebraic expression for $x(\omega)$. Now, every time we find the Laplace transform of some $x(t)$ as $x(s)$ we have to note the expression for $x(s)$ as well as the region of the s plane, where it is valid. Thus in the example just concluded, we see that it is only for $\sigma > -1$ that $x(s) = 1/(s+1)$ is valid.

(Refer Slide Time: 30:02)

L.T consists of 2 items of information

1. The expression for $X(s)$
2. The region of the s -plane where the expression holds

Consider $x(t) = e^{-2t}u(t) + e^{+t}u(t)$

$$X(s) = \frac{1}{s+2} + \frac{1}{s-1}$$

ROC: $\sigma > -2$ $\sigma > +1$

$X(s)$ will converge if each component of the sum separately converges $R_1 \cap R_2 = R$

The diagram shows the complex s -plane with a horizontal real axis and a vertical imaginary axis. Two vertical lines are drawn at $\sigma = -2$ and $\sigma = +1$. The region to the right of $\sigma = -2$ is shaded with diagonal lines and labeled R_1 . The region to the right of $\sigma = +1$ is shaded with horizontal lines and labeled R_2 . The intersection of these two regions, which is the region to the right of $\sigma = +1$, is labeled R .

So, the Laplace transform consists of two parts, consists of two items of information; the expression 1 is the expression for $x(s)$ into 2 the region of convergence the region of the s

plane where the expression holds alright. Now, let us just see what happens if we consider the Laplace transform of 2 functions simultaneously that means of the sum of 2 functions. Consider $x(t)$ equals $e^{-2t}u(t)$ plus $e^{-t}u(t)$ from the form of the Laplace transform equation it is clear that it is linear transform.

So, that the transform of the sum of two functions must be equal to the sum of the transforms, on this basis and knowing the Laplace transform as we just experimented with it for this expression. And this expression separately we can write that $X(s)$ equals $\frac{1}{s+2}$ plus $\frac{1}{s+1}$. So, we can write this but then there is the issue of the region of convergence now since we cannot directly common the region of convergence of entire $X(s)$.

Let us look at the region of convergence of the individual parts for this part clearly if you go back to the original function $e^{-2t}u(t)$ we find analogous arguing analogous with what we had earlier that $\sigma > -2$ must be greater than 0. That means σ must be greater than minus 2 σ must be greater than minus 2 is what this expression requires. Now, what does this expression require it requires with similar arguments that σ must be greater than plus 1, so in the s plane suppose we make plots of the region of convergence of first component function and of the second component function. So, for one of them it is this for the second one it is this and for the first one it is this $\sigma > -2$ and for the second one it is $\sigma > -1$.

So, it is this, this is what we get, so if we ask now what is reason for region of convergence of the combination then the answer is clear if $X(s)$ will converge will converge. If each component of the sum of the sum separately converges there is to say we have to look at the intersection of the convergence regions of the two terms, which comes out to be which I call this R_1 . If I call this R_2 then it comes out to be $R_1 \cap R_2$, which is just equal to R_2 , so R_2 where R_1 is this let me just denote this is in a more friendly way using different colours. So, let us say that this is R_2 and this is R_1 .

So, R_1 is in green and R_2 is in blue and $R_1 \cap R_2$ is the part which is has both by R_1 and R_2 . So, this is what we get when the Laplace transform of a sum of functions for each of which the Laplace transform and the individual regions of convergence are known. Now, let us take let us introduce ourselves to a rather surprising fact, let us consider $x(t)$ equal to $e^{-at}u(t)$ of minus t this is a function, which is

what is called left sided that means that for t greater than 0 its 0 or t less than 0 or non 0, so this is e to power minus $e t a t$.

(Refer Slide Time: 37:20)

The image shows a whiteboard with handwritten mathematical derivations for the Laplace transform of a left-sided exponential function. The steps are as follows:

$$x(t) = e^{-at} u(-t)$$

$$X(s) = \int_{-\infty}^0 x(t) e^{-st} dt = \int_{-\infty}^0 e^{-at} e^{-st} dt$$

$$\dots \frac{-1}{s+a} \quad (\sigma + a) < 0$$

$$\underline{\underline{R: \sigma < -a}}$$

$$e^{-at} u(-t) \rightarrow \frac{-1}{s+a} \quad \text{then} \quad -e^{-at} u(-t) \rightarrow \frac{1}{s+a}$$

$$\left. \begin{aligned} x_1(t) = e^{-at} u(t) &\rightarrow \frac{1}{s+a} : \sigma > -a \\ x_2(t) = -e^{-at} u(-t) &\rightarrow \frac{1}{s+a} : \sigma < -a \end{aligned} \right\}$$

So, let us try to find $X(s)$ equals integral minus infinity to infinity $x(t) e^{-st} dt$ which simplifies along lines. Similarly, this earlier describes that its minus infinity to 0 thus the area of non zeroness of the argument e to the power minus $a t e$ to the power minus $s t d t$, which after simplification comes to 1 by minus 1 by s plus a with a region of convergence that requires that σ plus a must be negative. That means σ must be less than minus k , so this is the definition of the this is the this describes of R O C for this function σ must be less than minus a . Then the algebraic expression is that $x(s)$ equals this, now this looks familiar the expression looks.

Familiar in fact since the Laplace transform is linear as is evident from inspection you will see that if e to the power minus $a t u$ of minus t goes to minus one by s plus a then minus e to the power minus $a t u$ of minus t must go to one by s plus a . But if we recall e to the power minus $a t u t$ went to 1 by s plus a we solve this a few minutes ago this means that two totally different functions namely this and the second one v minus e to the minus $a t u$ minus t also go to one by s plus a .

This seems to such as that unlike the continuous time Fourier transform $x(s)$ is not unique different functions $x(t)$ can have the same Laplace transform that is not really true. Because recall we have said right at right little while ago that the Laplace transform of

function has 2 items of information. What we are now trying to do is to ignore the second item of information what we have written down. Here is only the first item of information, which is the algebraic value the expression for x of t for x of s we should also note that for this function the upper 1 sigma must be greater than minus a .

Whereas, here sigma must be less than minus a as we just found that means that their the expressions are same. The region of convergence are difference this is what helps us in distinguish between the first x t , which I will say I will call this as x 1 t and x 2 t x 1 t is this and x 2 t is this their expressions are the same. But their regions of convergence are different so as long as we take both items of information into consideration. The Laplace transform does remain a unique part as s t to x s .

Now, with this in mind with this in hand we will see what we can what more we can do to learn the Laplace transforms. Let us start with a few examples, now the fact is that for our purposes of use it is sufficient to consider Laplace transforms only of certain standard functions, which are related to the exponentials. Thus we will consider for example, we have already done e to the minus a t u t and e to the power minus e to the power minus a t u minus t for these functions we already have the Laplace transforms now we will consider I did not solve this in detail.

(Refer Slide Time: 42:09)

Handwritten Laplace transform formulas on a whiteboard:

$$\cos \omega_0 t u(t) \rightarrow \frac{s}{s^2 + \omega_0^2}; \sigma > 0.$$

$$\sin \omega_0 t u(t) \rightarrow \frac{\omega_0}{s^2 + \omega_0^2}; \sigma > 0.$$

$$e^{-at} \cos \omega_0 t u(t) \rightarrow \frac{s+a}{(s+a)^2 + \omega_0^2}; \sigma > -a$$

$$e^{-at} \sin \omega_0 t u(t) \rightarrow \frac{\omega_0}{(s+a)^2 + \omega_0^2}; \sigma > -a$$

$$\frac{t^{n-1}}{(n-1)!} e^{-at} u(t) \rightarrow \frac{1}{(s+a)^n}; \sigma > -a.$$

But we will consider $\cos \omega_0 t u(t)$ this comes out to have a Laplace transform of s by s squared plus ω_0 not squared with sigma greater than 0. As the R O C co sine

$e^{-at} \cos \omega t$ comes out to have a transform $\frac{\omega}{s^2 + \omega^2}$ for $\sigma > 0$ again is just a listing it is just a listing of the standard forms for which we look for Laplace transforms. Next suppose, you had $e^{-at} \sin \omega t$ that would give you a transform of $\frac{\omega}{s^2 + \omega^2}$ for $\sigma > 0$.

Similarly, $e^{-at} \cos \omega t$ would have a transform of $\frac{s}{s^2 + \omega^2}$ for $\sigma > 0$. Suppose, we had $t^{n-1} e^{-at}$ this would give us a Laplace transform of $\frac{(n-1)!}{s^n}$ for $\sigma > 0$. So, these are the general forms in terms of which most of the other simpler expressions for which we look for Laplace transforms will be created.
