**Error Control Coding: An Introduction to Convolutional Codes** 

# Lecture – 1 B Introduction to Error Control Coding-II

# by Prof. Adrish Banerjee Department of Electrical Engineering, IIT Kanpur

Welcome to the course on error control coding, an introduction to linear Convolutional codes. So we will continue our discussion on introduction to error control codes. In this lecture we are going to talk about, where does error control coding fits in, in the digital communication system. So we will start with the block diagram of a digital communication system.

(Refer Slide Time: 00:39)

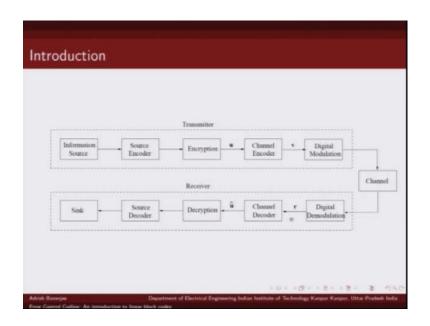

So this is a block diagram of a digital communication system. So we have our information source, which is basically the message that we want to transmit. The first block that you see is Source Encoder, now Source Encoder essentially does data compression, it tries to represent the source efficiently in terms of minimum number of bits required to represent the source, so that is

basically done by this block source encoder. Now once you have represented you have compressed your source.

The next block is basically data encryption, this is for secrecy and then the next block which is our, of our interest here in this course is what is known as Channel Encoder. So it takes into account as input information bits and gives us as output the coded bits. We typically use the symbol u to denote information sequence and the symbol v to denote the coded sequence. So this course essentially will deal with this block of the digital communication system, essentially how to design good error correcting codes and properties of error correcting codes.

Now once we have this encoded sequence you want to send these bits over a communication link so you need to do Digital Modulation, once you have modulated your signal you want to send it over the transmission medium which is a channel. And then, at the receiver you just have the reserve, reverse operation. So once you get a noisy version of the receive sequence you would like to demodulate the signal and the demodulated output is then fed to Channel Decoder, whose job is to estimate information sequence.

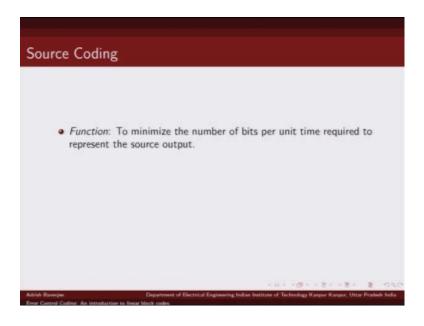

(Refer Slide Time: 02:59)

From the receive sequence, we use the notation r for receive signal. A received inputs demodulate signal and we will use û to denote the estimated information bits. Now if u is equal to û there is no error, however if u is not same as û then there are decoding errors. Now once you decode the information bits then you would like to de-encrypt to get back your plain text data so this de-encryption is opposite action of encryption and once you get back your plain text you would like to decompress the signal to get back your original source signal, so that's basically in a nut shell the broad block diagram of a digital communication system.

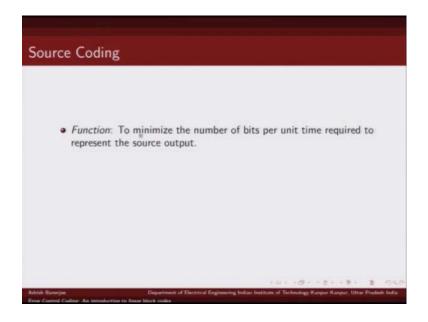

So we can see basically in this course we are interested in this block, we are interested in this block and of course, we are interested in this block as well because our error control coding strategy depends on what sort of channel we are sending our information bits forward, okay? So I will now explain a little bit more detail about each of these block diagrams.

(Refer Slide Time: 04:29)

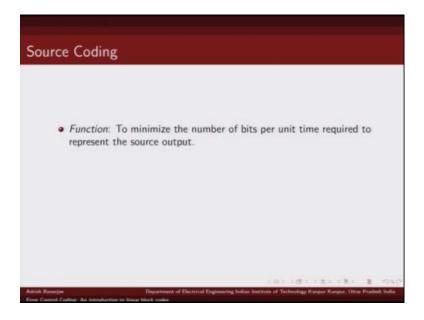

So the first is basically our source encoder and as I said this is essentially does source compression, source coding.

(Refer Slide Time: 04:39)

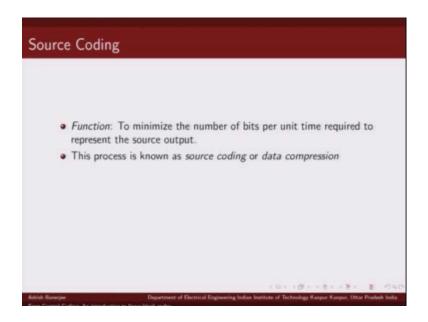

And its objective is to represent your source in minimum number of bits required. As we know that our source typically for example English text. There are lot of in built rendencies in the text for example q, the letter q is always followed by u. So if you want to fast bit let us say some word starting with q, we do not need to transmit u because in English text because q will be always followed by u. So like that there are lot of unnecessary rendency built in, into the source which we would want, which we would like to get rid of and that is the job of source encoder. So the source encoder will like to represent our source compactly in a minimum number of bits.

(Refer Slide Time: 05:33)

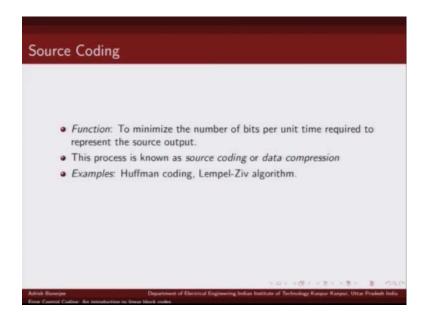

Required it that's basically the objective of the source encoders it does basically data compression.

(Refer Slide Time: 04:41)

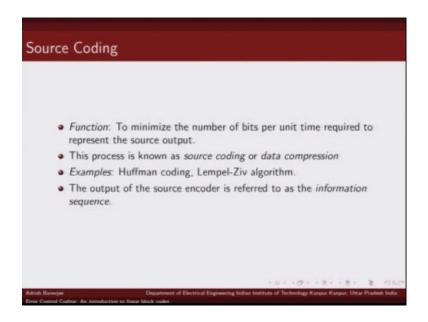

(Refer Slide Time: 05:44)

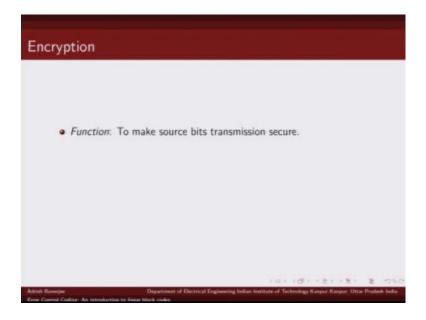

Some examples, of data compression techniques as basically Huffman coding, Lempel-Ziv Algorithm. We would not be talking about this because this topics of interest in information theory. We will restrict our discussion to coding theory topics in this course.

(Refer Slide Time: 06:04)

And as I said basically the input to our channel encoder we are referring it as information sequence.

(Refer Slide Time: 06:17)

Now the next block was of encryption and the objective of the encryption is to make the data or made the bits secure. So that unwanted users should not be able to find out.

(Refer Slide Time: 06:33)

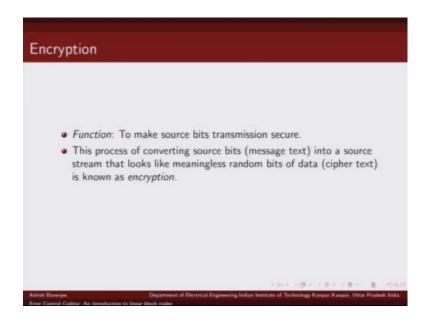

What has been transmitted.

(Refer Slide Time: 06:34)

So in this encryption process what we do, we convert our source bit into what we call as cipher text. So we basically, encryption takes our source bits and it converts it into some, some random looking bits.

(Refer Slide Time: 06:56)

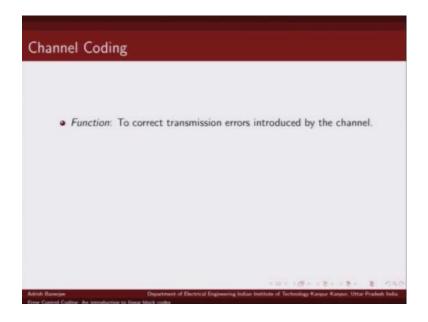

Which for somebody who does not have key would appear as a random meaningless data, so it basically converts your message text into what we call cipher text, that is basically encryption.

(Refer Slide Time: 07:09)

And examples of encryption is Data Encryption Standard, Advance encryption standard, RSA system. The next block was of channel encoder.

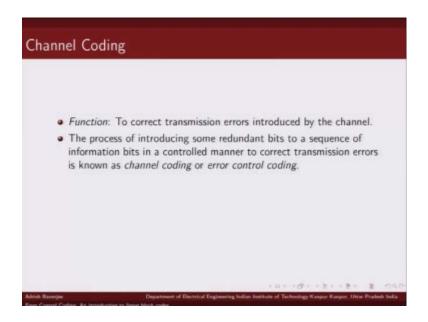

(Refer Slide Time: 07:22)

Now this is of interest in this course and what is objective of this block, we would like to introduce additional redundancies into the source and with the help of these redundant bits we would like to detect and correct error induced by transmission errors or storage errors, basically we would like to correct or detect those errors. Now if you are wondering why cannot we use the inherent redundant bits which are available in a source and why, why do not we just get rid of source encoder and channel encoder, just use the plain source which has inherent some redundant bits.

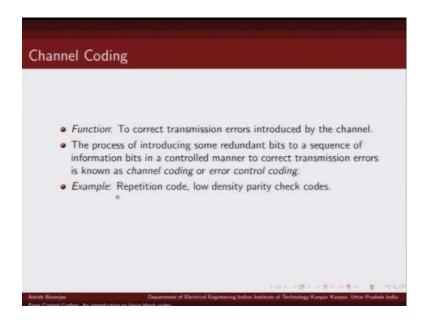

The problem with this is we do not have any control over those redundant bits which are inherent in a source. Whereas in our channel encoder the redundant bits that we are adding have been carefully designed in such a way so as to detect or correct errors.

(Refer Slide Time: 08:22)

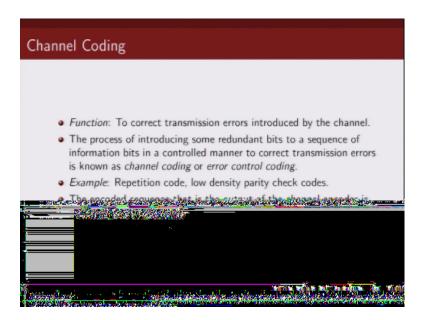

So this process of basically adding some redundant bits which we call as parity bits to our message bits is basically, this process is known as channel coding or error control coding. And this is essentially done to detect or correct error which as caused by transmission medium.

(Refer Slide Time: 08:45)

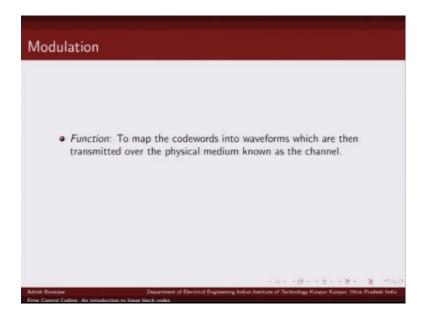

In the last lecture I already gave an example of a simple, very simple code repetition code there are throughout this course we are going to talk about some other examples of.

(Refer Slide Time: 08:59)

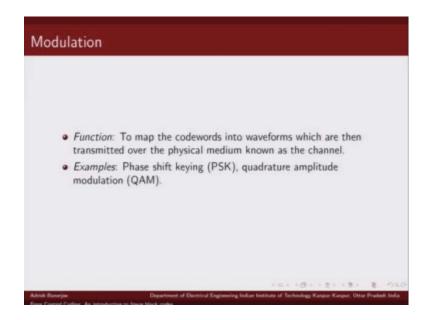

Error cractic goods. We use the term codeword to denote the encoded sequence out of the channel encoder.

(Refer Slide Time: 09:09)

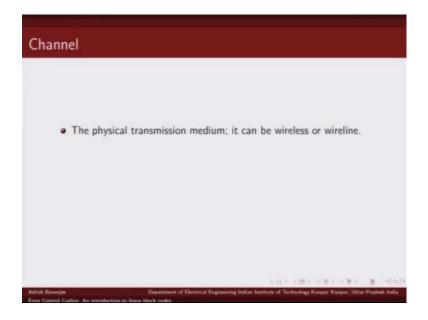

Now once we have, have the encoded sequence we would like to transmit that sequence over a communication link so what we need to do is modulation so, modulation maps these code words into actual wave forms which are sent over a communication link. And you are familiar with, I am sure you are familiar with digital modulation techniques such as BPSK, Binary Phase Shift keying, Quadrature Amplitude Modulation or you have also studied about.

(Refer Slide Time: 09:40)

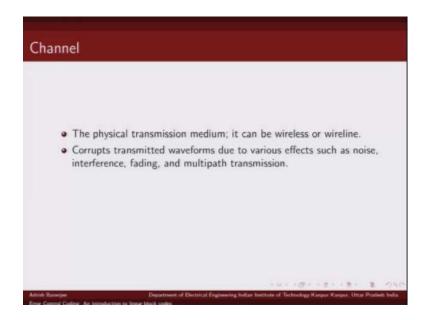

Analog modulation schemes also.

(Refer Slide Time: 09:43)

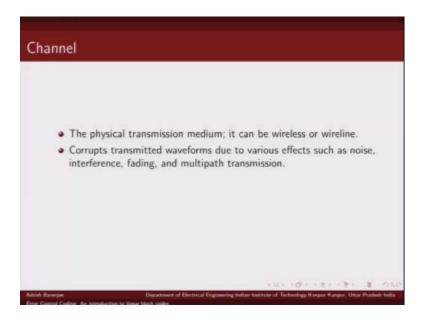

The next block in our block diagram was a channel. So what was channel, channel was essentially our transmission medium over which we were sending our coded bits. So the physical transmission medium is known as channel and this could be a wired medium for example, our old fashioned phones, or it could be wireless medium.

(Refer Slide Time: 10:13)

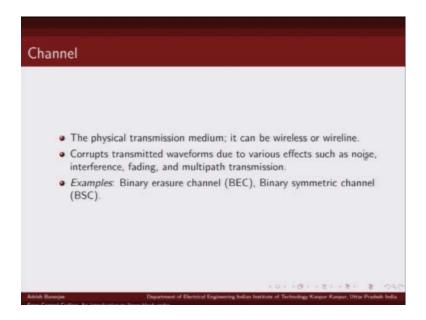

Now what effect does channel has on the transmitted sequence. As we know basically.

(Refer Slide Time: 10:21)

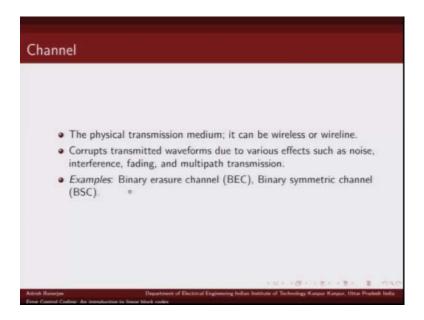

The channel corrupts the signal in multiple ways. For example, noise this basically noise.

(Refer Slide Time: 10:27)

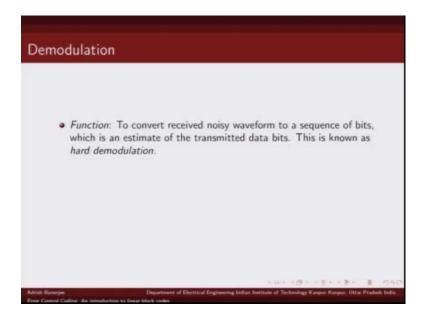

Deteriorates the signal interference is basically because multiple signals clashing with each other fading basically if you are let us say under some building or something you will not get a very good signal so that is some example of fading, shadowing, multipath transmission, when you have reflections from multiple buildings what you receive you have sent just one signal you get multiple copies with varying attronation and delay spread, so essentially channel corrupts our signal that we are transmitting and it results in errors. And there are various models of channels which are very popularly used.

(Refer Slide Time: 11:17)

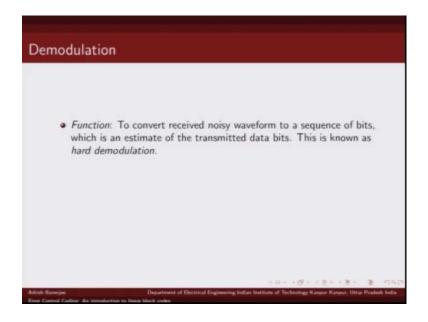

In the last lecture we did talk about Binary erasure channel which is a very good example for two model basically packet data communication system and another channel model what we talked about was Binary symmetric channel, it is a very simple channel model typically used to model added to white across your noise channel with hard demodulation. So these are some examples of channel models.

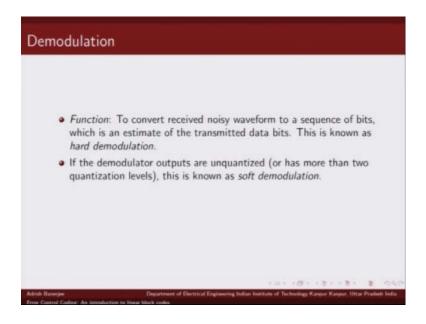

(Refer Slide Time: 11:46)

Now the next block in our digital communication system was demodulation so what does demodulation does, so as a result of passing through the communication channel what we get is a very noisy wave form and from that noisy waveform essentially you want to get an estimate of what the transmitted bits are. Now when we try to demodulate or get back original bits zero's and one's that's basically what is known as hard demodulation.

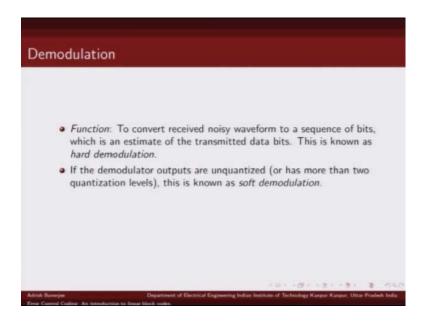

(Refer Slide Time: 12:19)

This also something called soft demodulation. What if we are getting received noisy values of the receive sequence instead of quantizing them directly to zeros and ones. If we keep bit unquantized then this type of demodulation is known as soft demodulation. Now what is the advantage of soft demodulation? In hard demodulation we basically lose lot of information, for example let us say you consider binary transmission you are sending zeros and ones and let us say you are using binary phase shift key. So let us consider scenario where zero is map to plus one and one is map to minus one.

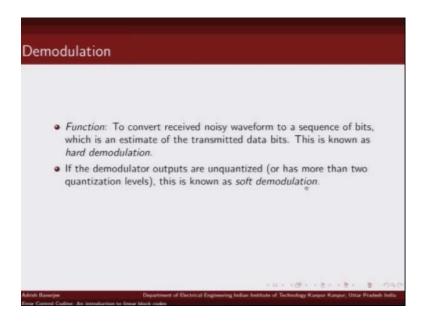

And let us say you received, received symbol was point zero one. Now see what doing hard demodulation.

(Refer Slide Time: 13:17)

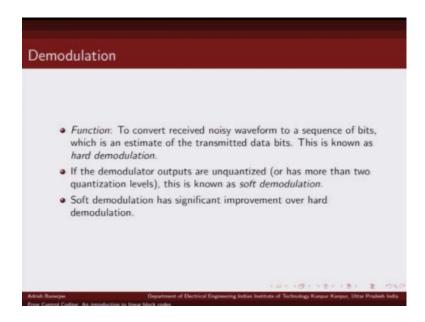

You would demodulate to be because its distance sectional will be zero, you will demodulate it to be zero bit transmitted. But point zero one could very well be could have been minus point zero one if the noise would have been little bit like the sequence, so it is very close to zero so in hard demodulation you lose that information. So if instead of just directly mapping our receive sequence it was zero point zero one to zero if you would have just also kept some idea about how sure we are, or how close we think it is to zero or one then that information is useful. And that is captured in soft demodulation.

(Refer Slide Time: 14:04)

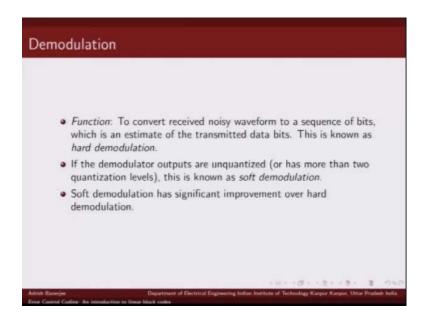

So in soft demodulation we would not just map point zero, one to zero we will just see it is zero with probability point five one or one with probability five point four nine just lay like I am just giving an example so we lose some information when we go for hard demodulation.

(Refer Slide Time: 14:29)

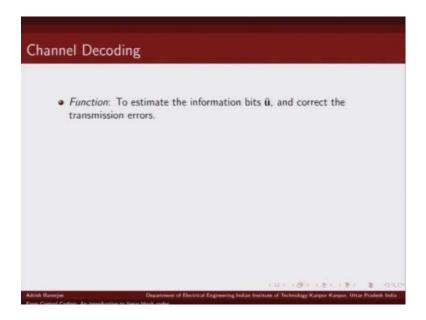

So typically basically when you will see basically if we do soft demodulation our performance is roughly two DB better than if you were just doing hard demodulations.

(Refer Slide Time: 14:44)

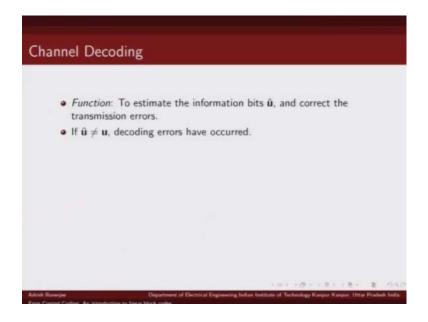

So most of the modern coding techniques we will basically we will be doing soft demodulation and we will pass on these bits soft values to the decoder, channel decoder and we will then ask it to do error correction or error detection.

(Refer Slide Time: 15:02)

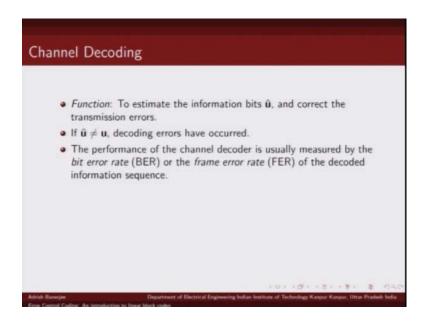

Softer demodulation we have channel decoding, as I said the channel decoder objective is to estimate what was the transmitted information sequence from the received coded sequence.

(Refer Slide Time: 15:21)

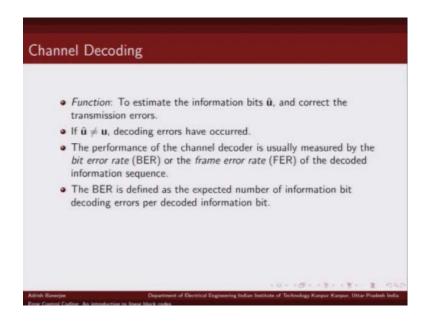

And its objective is also to correct any errors which was caused by transmission error. So when do we say an error has occurred, if our decoded bit is not same as transmitted bit we say that decoding errors have occurred.

(Refer Slide Time: 15:46)

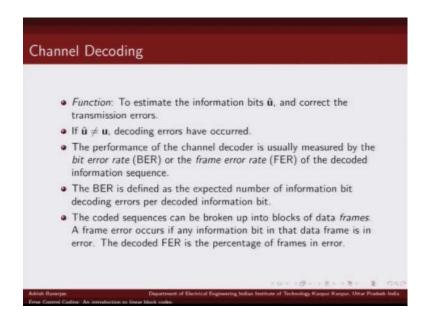

And how do we quantify these decoding errors, we quantify these decoding errors using what we call bit error rate or frame error rate. So performance of error correcting codes is typically evaluated using these bit error rate and frame error rate. So what is bit error rate and frame error rate?

(Refer Slide Time: 16:11)

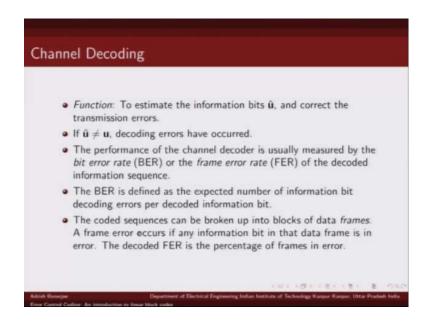

So we define bit error rate as the expected number of information bits that are decoded to be in error. So for example if you transmit n information symbols and out of them x basically our bits are received in error so the bit error rate would be x by n.

(Refer Slide Time: 16:40)

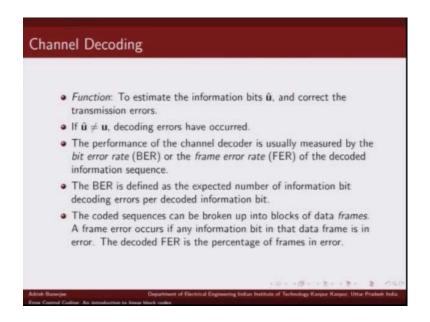

Similarly when we are talking about packet data communication we are interested in so for example if any of the bits in the packet, whole packet is an error, we say the packet is in error or the frame is in error. So frame error rate is defined as number of frames, or number of packets in error divided by total number of packets that we have transmitted. So a frame error rate occurs if,

(Refer Slide Time: 17:07)

Any of the bits in your data frame or in your packet is received in error. So it is the percentage of frames that are in error. This is known as frame error rate. So when we compare performance of different error correcting codes what we do is we plot on the y axis bit error rate or frame error rate versus SNR signal to noise ratio basically. So how is the performance of when we increase signal to noise ratio, how does our error correcting codes perform that is how basically we compare to error correcting.

(Refer Slide Time: 17:55)

That is one of comparing to error correcting codes.

(Refer Slide Time: 17:57)

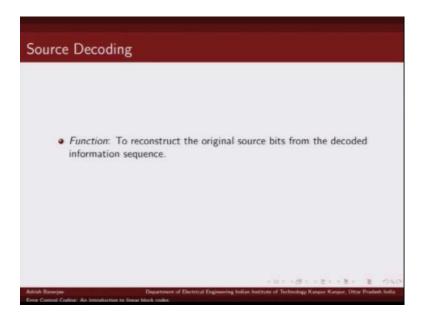

After channel decoder we have this de-encryption block and as I said its objective is to recover pack the plain text from the cipher text.

(Refer Slide Time: 18:09)

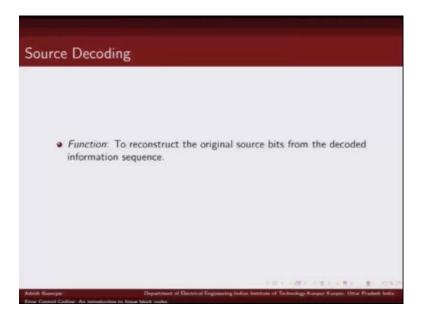

And essentially the security of the system lies in the key.

(Refer Slide Time: 18:16)

And finally we would like to get back our original source because remember in source encoder what we did was we did data compression so we have been processing this compressed data. So from the compressed data we would like to get back our.

(Refer Slide Time: 18:32)

Original source and that is basically the source decoder. So its deconstruct back the original source bits from the decoded information sequence. And of course if there are errors in our final you know decoded sequence would not be same as what was transmitted.

(Refer Slide Time: 18:52)

Source Decoding
<ul> <li>Function: To reconstruct the original source bits from the decoded information sequence.</li> <li>Due to channel errors, the final reconstructed signal may be distorted.</li> </ul>
