Lecture - 18
Fisher Linear Discriminant

Hello and welcome to this next talk in the course and pattern technician. We have been considering linear classifiers for last so many lectures. Specifically, in the last few lectures we have been looking at the linear least squares approach both for classification and regression. Least square approach minimizes some of square of errors and we seen how we can use that to learn linear models and will continue with that now.

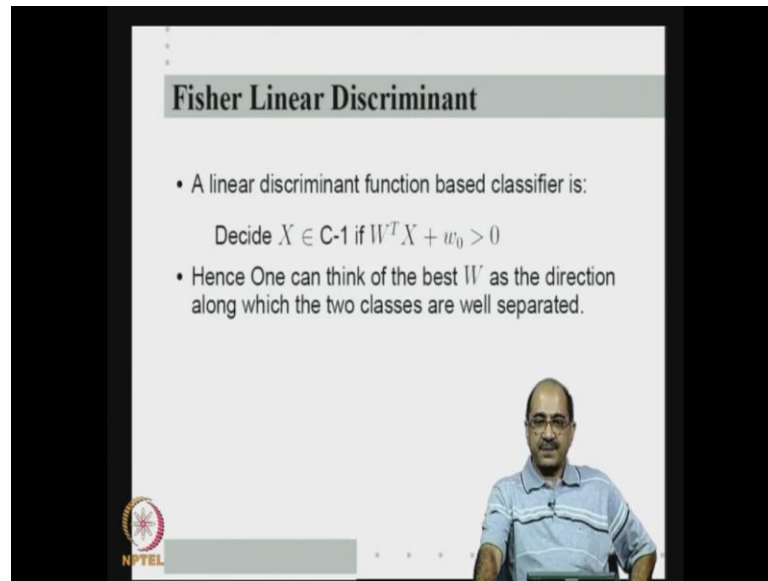

(Refer Slide Time: 00:51)

The image shows a video frame from a lecture. On the left, there is a presentation slide titled "Recap" in a grey header. The slide contains four bullet points: "We have been considering the linear least squares method for learning classifiers and regression functions.", "The least squares method is based on the criterion of minimizing mean squared error.", "This is a good way to fit linear models to given data.", and "As mentioned in the previous lecture, Fisher Linear Discriminant is another way of constructing linear classifiers." In the bottom right corner of the video frame, there is a small inset showing the speaker, Prof. P. S. Sastry, a man with glasses wearing a light blue striped shirt. In the bottom left corner of the slide, there is a small NPTEL logo.

So, the least square method is based on the criterion of minimizing mean squared error. And we see how we can derive linear least squares algorithm for classifiers for learning regression functions. And we also looked at logistic regression of learning classifiers. There is one other approach to learn linear classifier which we very briefly mentioned at the end of the last class and that is the fisher linear discriminant while, least squares is also a good way of learning linear models and is a very very standard way. Fish linear discriminant actually somewhat predates the least squares approach, it is a very interesting approach to learning a linear classifiers. And today we will be looking at fisher linear discriminant as a method for constructing linear classifiers.

(Refer Slide Time: 01:54)

The image shows a video frame from an NPTEL lecture. In the background, a presentation slide titled "Fisher Linear Discriminant" is displayed. The slide contains the following text:

- A linear discriminant function based classifier is:
Decide $X \in C-1$ if $W^T X + w_0 > 0$
- Hence One can think of the best W as the direction along which the two classes are well separated.

In the bottom right corner of the video frame, a man with glasses and a light blue shirt is visible, presumably the lecturer. The NPTEL logo is visible in the bottom left corner of the slide area.

Any linear discriminant function based classifiers essentially, given a feature vector X ; it decides that X belongs to class 1 if, $W^T X + w_0 > 0$ for some given W and w_0 . If $W^T X + w_0$ is greater than 0 is one class less than 0 another class. That is what a linear classifier linear discriminant function bayes classifiers is about. Now, because W is a vector, we can take it as a direction in the d , the appropriate space. Then, $W^T X$ is nothing but the projected value of X onto the direction W . So, if I think of this inequality $W^T X > -w_0$ and if it is a good classifier. What it means is, if I take any X that belongs to class 1 and projected it onto W , the projected value, $W^T X$ is greater than $-w_0$. And on the other hand, if I take any X in class C_0 and project it on to the direction W then, the projected value $W^T X$ less than $-w_0$.

So, essentially what a linear discriminant function is doing is looking for a direction W . Such that, if I project the features vectors on to the direction then, along that direction the 2 class are well separated. On that direction there will be some threshold in this case $-w_0$, some point along that direction. Such that, the projected versions of all features vectors are 1 class will be on one side of this threshold whereas, the projected versions are all the features vectors are the other class will be on the other side of this threshold along the direction W . So, we can think of the best W for a linear classifier to be a direction along which the 2 classes are separated. So, we are looking for a particular direction feature space. Such that, if you project all the vectors onto the directions, all the

feature vectors onto direction, I get a very good separation between the feature vectors of the 2 classes.

(Refer Slide Time: 04:00)

Fisher Linear Discriminant

- A linear discriminant function based classifier is:
Decide $X \in C-1$ if $W^T X + w_0 > 0$
- Hence One can think of the best W as the direction along which the two classes are well separated.
- We project the data along the direction W . Separation between points of different classes in the projected data is a good way to rate how good is W .
- Such a method is called Fisher Linear Discriminant.

NPTEL

So, the idea is that we project the data along the direction W . And separation between points of different classes in the projected data is a good way to rate how good W is. So, now to learn a good W I can take different W 's, project the data onto these W 's, and I am asking which W is there which will maximize the separations between the classes. This is the basic idea fisher linear discriminant.

(Refer Slide Time: 04:28)

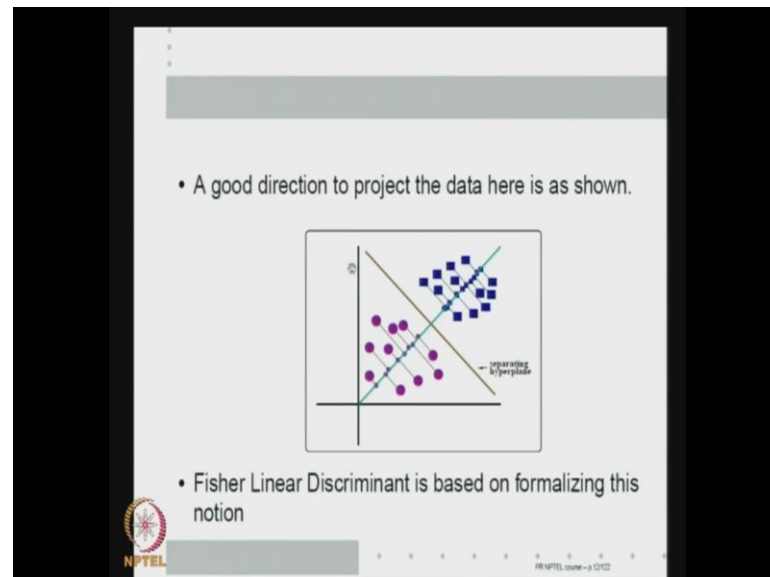

• Consider the following 2-class example

NPTEL

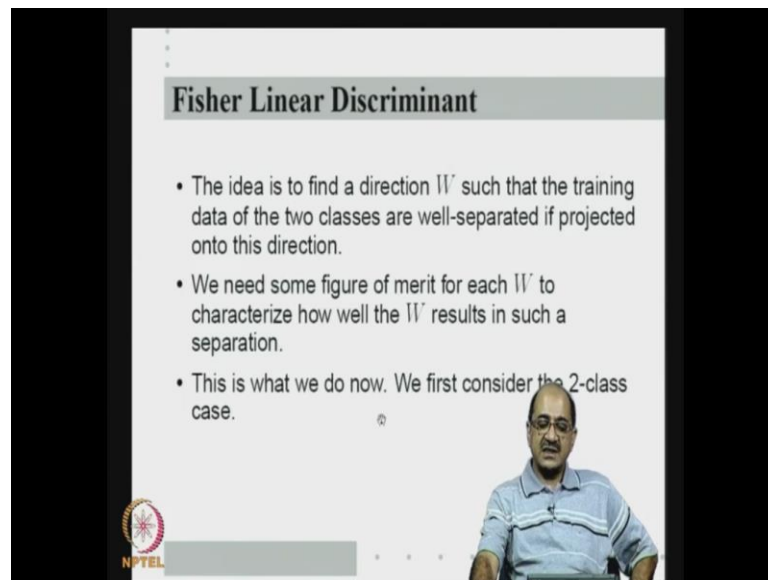

Before we go into the mathematical details let us look at a simple example. Let us say this is the 2-class problem: Reds are 1 class and blues are another class. If I project all data for example, onto the X axis, the reds and blues get inter mingled in X axis. Similarly, if I project it on to the y axis also they get inter mingled.

(Refer Slide Time: 04:47)

But, we can easily find a direction namely, this line. If I project the data along this line, as you can see; if I recode my 2 dimensional features vectors as 1 dimensional feature vectors by projecting them along this direction. Then, all 1-class patterns are one side and all other class patterns are other side. The actual separating hypo plane is perpendicular to this direction. So, If I think of W as this direction; obviously, W is perpendicular is the normal to the separating hypo plane. So, that will be separating hypo plane. So, I can think of finding the best W as finding a direction along which you have to project the data so that all the feature vectors have 1 class in the projected space or well separated from the feature vectors of the other class. So, fisher linear discriminant is a way of formalizing this notion of finding the best direction to project so that the 2 classes get well separated.

(Refer Slide Time: 05:49)

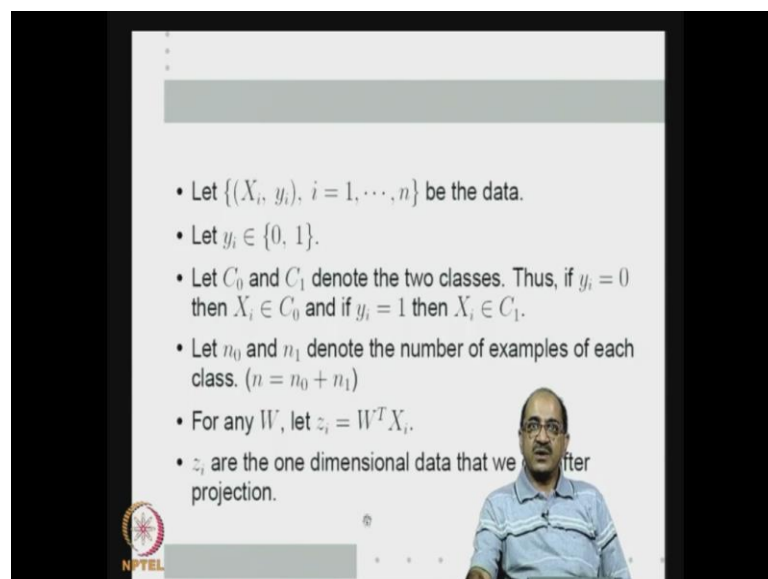

Fisher Linear Discriminant

- The idea is to find a direction W such that the training data of the two classes are well-separated if projected onto this direction.
- We need some figure of merit for each W to characterize how well the W results in such a separation.
- This is what we do now. We first consider the 2-class case.

NPTEL

So, what does fisher linear discriminant do? We want to find a direction W , such that the training data the 2 classes are well separated if projected onto this direction. So, to do this off course we have to find a way of formalizing this notion of what you mean by well separated. So, essentially we need to have a figure of merit some some number that I can assign to W . So, I want some J of W which assigns a number to a W to figure of merit. Such that, the number tells me how well projection on that W will result in proper separation.

(Refer Slide Time: 06:29)

- Let $\{(X_i, y_i), i = 1, \dots, n\}$ be the data.
- Let $y_i \in \{0, 1\}$.
- Let C_0 and C_1 denote the two classes. Thus, if $y_i = 0$ then $X_i \in C_0$ and if $y_i = 1$ then $X_i \in C_1$.
- Let n_0 and n_1 denote the number of examples of each class. ($n = n_0 + n_1$)
- For any W , let $z_i = W^T X_i$.
- z_i are the one dimensional data that we get after projection.

NPTEL

So, will do that, we will formalize this by first considering a 2-class case. So, let us get a notion right first as we been looking at our data is always X_i, y_i , this is our training data, we have n samples. X_i are the feature vectors there in $r d$ and y_i is the class label. We are considering 2-class. So, let us assume y_i 0 and 1. And this, 2 classes we will denote by C_0 and C_1 .

So, what it means is when y_i is 0 then, I can say X_i belongs to C_0 and when y_i is 1, I can say X_i belongs to C_1 . Let us say, out of the n samples, n_0 training samples are in class 0 that is C_0 and n_1 training samples from class C_1 . Obviously, n is equals to n_0 plus n_1 . For given any W , let z_i denote $W^T X_i$. So, z_i are the projected data along any direction W . So, z_i are the one dimensional data that we get after projection. This is our notation.

(Refer Slide Time: 07:35)

• Let M_0 and M_1 be the means of data from the two classes:

$$M_0 = \frac{1}{n_0} \sum_{X_i \in C_0} X_i; \quad M_1 = \frac{1}{n_1} \sum_{X_i \in C_1} X_i$$

The corresponding means of the projected data would be

$$m_0 = W^T M_0 \quad \text{and} \quad m_1 = W^T M_1$$

NPTEL

NPTEL course - 6.03.02

Let us say M_0 and M_1 denotes the means of the data from 2 classes. So, that essentially sample means so, M_0 is simply the mean of all X_i that are in class 0 and there in M_0 . So, $\frac{1}{n_0} \sum_{X_i \in C_0} X_i$ will give me the sample mean of the class 0 data vectors. Similarly, $\frac{1}{n_1} \sum_{X_i \in C_1} X_i$ gives me the sample mean of class 1.

So, the corresponding means of the projected data, would be what? If I project X_i onto W , I get $W^T X_i$. So, if I take mean of $W^T X_i$ will be same as $W^T M_0$. So, on the projected data let us denote the mean by small m_0 . So, the

mean small m_0 will be $W^T \text{capital } M_0$ and small M_1 will be $W^T \text{transpose capital } M_1$. So, these are the means of the projected data when data is projected onto direction W .

(Refer Slide Time: 08:42)

The slide contains the following text:

- The difference $(m_0 - m_1)$ gives us an idea of the separation between samples of the two classes after projecting the data onto the direction W .
- Hence, we may want a W that maximizes $(m_0 - m_1)^2$.
- However, we have to make this scale independent.
- Also, the distance between means should be viewed relative to the variances.

The lecturer, a man with glasses wearing a light blue shirt, is visible in the bottom right corner of the video frame.

So, if I want good separation, what I mean is the difference between M_0 and M_1 should be large. So, we can say M_0 minus M_1 or M_1 minus M_0 is really does not matter gives us a good idea of the separation between the samples of 2 classes when the data is projected on to the direction W . So, we can say a good direction W is one which maximizes the separation. So, we may want W that maximizes M_0 minus M_1 whole square because that gives me large separation. But, there are 2 caveats here; just maximizing M_0 minus M_1 is not a good idea. Why? What is M_0 minus M_1 ? $W^T \text{transpose capital } M_0$ minus $W^T \text{transposes capital } M_1$ whole square. So, is $W^T \text{transpose capital } M_0$ minus $W^T \text{transpose capital } M_1$ whole square.

So, just by scaling W , I can increase this difference but, that is meaningless. A scale factor, a positive scale factor makes no difference to the linear classifier. So, first we have to find some function that is scale independent. But, more importantly what is good separation; depends on how much data spread is there. We are only looking at the distance between the means as we already seen we can consent bayes classifiers normal class conditional densities. Essentially, the difference between the mean relative to the variances is what tells us whether the classes are well separated or not. So, to look at the

distance between the means m_0 minus m_1 in relative to the variances of the 2 classes. So, that is how we have to formulate our objective function W .

(Refer Slide Time: 10:34)

• Define

$$s_0^2 = \sum_{X_i \in C_0} (W^T X_i - m_0)^2; \quad s_1^2 = \sum_{X_i \in C_1} (W^T X_i - m_1)^2$$

These give us the variances (upto a factor) of the two classes in the projected data.

• We want large separation between m_0 and m_1 relative to the variances.

NPTEL

NPTEL course - 63632

So, let us first calculate that is something like variance. As define s_0^2 to be $W^T X_i - m_0$ whole square. $W^T X_i$ is the projected data that is z_i . This is summation or X_i belongs to C_0 , for all X_i in C_0 the mean of the projected data is m_0 . So, $W^T X_i - m_0$ whole square, sum dot X_i belongs to C_0 , is like the variance of the projected data of class C_0 . Say like because I dint put 1 by m_0 , I could have put 1 by m_0 but, we did not. So, this essentially just accept for a multiplicate, for a constant multiplicate factor; these essentially variance of the projected data from class C_0 .

Similarly, if I define s_1^2 to be summation or X_i belongs to C_1 $W^T X_i - m_1$ whole square because m_1 is the mean of the projected data of class 1. This is accept for multiplicative factor if the variances is the projected data in the for class 1. So, what we want? We want large separation between m_0 and m_1 relatively to the variances. That is our objective. So, I can formulate this as a objective function for W as follows.

(Refer Slide Time: 11:50)

- Hence we can take our objective to be to maximize

$$J(W) = \frac{(m_1 - m_0)^2}{s_0^2 + s_1^2}$$

- We now rewrite J into a more convenient form.
- We have

$$\begin{aligned} (m_1 - m_0)^2 &= (W^T M_1 - W^T M_0)^2 \\ &= W^T (M_1 - M_0) (M_1 - M_0)^T W \end{aligned}$$

So, we say we want to maximize J of W , with J of W defined as m_1 minus m_0 whole square by s_0 square plus s_1 square. So, we want large separation m_1 minus m_0 whole square, relative to the variances s_0 square plus s_1 square. By the way even though this equation looks as if there is no W at the right hand side, you know all m_0 , m_1 , s_0 , s_1 everything depends on W ; s_0 , s_1 square dependent on W .

Right; s_0 , s_1 square dependent on my m_0 depends on W . So, this is a function of W . So, we want to maximize the difference between the means in the projected space relative to the variances. This off course is also scale independent that is not really evident right now but, will see it by rewriting this in a more convenient form. To rewrite this in a more convenient form; let us start with a numerator.

What is m_1 minus m_0 whole square? m_1 is W transpose capital M_1 minus W transpose capital M_0 whole square. This I can write as W transpose into M_1 minus M_0 the whole square. So, because W transpose M_1 minus M_0 is a vector, I can always write it as W transpose M_1 minus M_0 into M_1 minus M_0 transpose W . So, m_1 minus m_0 whole square can be written as W transpose M_1 minus M_0 , M_1 minus M_0 transpose W . M_1 is M_1 and M_0 are the means of the data, if data is $r \times d$ these are d vectors. Recall that our notation is all vectors are column vectors. So, m_1 minus m_0 is a d by 1 vector, M_1 minus M_0 transpose is a 1 by d vector. So, this is a matrix. So, this often called the outer product matrix for any 2 vectors.

(Refer Slide Time: 13:51)

The slide contains the following text:

- Thus we have $(m_1 - m_0)^2 = W^T S_B W$ where
$$S_B = (M_1 - M_0)(M_1 - M_0)^T.$$
- Here, S_B is a $d \times d$ matrix (note that $X_i \in \mathbb{R}^d$).
- It is called *between class* scatter matrix.
- We can similarly write s_0^2 and s_1^2 also as quadratic forms.

The lecturer is a man with glasses, wearing a light blue striped shirt, standing in front of the slide. The NPTEL logo is visible in the bottom left corner of the slide.

So, I can write; $m_1 - m_0$ whole square as W transpose some matrix into W . So, I can write $m_1 - m_0$ whole square as W transpose, thus called the matrix S subscript B . So, W transpose $S_B W$. Whereas, B is $M_1 - M_0$, $M_1 - M_0$ transpose. As I said this is a d by 1 vector, this is a 1 by d vector so, this is a d by d matrix. Given any vector x x transpose is called a outer product. An outer product is always a symmetric matrix. Also, I hope all of you remember that the outer product is a rank 1 matrix because all columns are multiple by the columns. So, is a rank 1 matrix.

So, such a matrix is d , this is a d by d matrix because our features vectors are on d . This matrix S_B is often called between classes scatter matrix. So, I can write $m_1 - m_0$ whole square as a quadratic form involving the matrix S_B which is the between class scatter matrix which is defined by this. In the similar way, I can write s_0 square and s_1 square also as quadratic forms.

(Refer Slide Time: 15:05)

We have

$$\begin{aligned}
 s_0^2 &= \sum_{X_i \in C_0} (W^T X_i - W^T M_0)^2 \\
 &= \sum_{X_i \in C_0} [W^T (X_i - M_0)]^2 \\
 &= \sum_{X_i \in C_0} W^T (X_i - M_0) (X_i - M_0)^T W \\
 &= W^T \left[\sum_{X_i \in C_0} (X_i - M_0) (X_i - M_0)^T \right] W
 \end{aligned}$$

So, let us try to do that now. s_0^2 by definition is $W^T X_i - W^T M_0$ whole square. We know M_0 is W^T capital M_0 . So, s_0^2 is $W^T X_i - M_0$ whole square summed over X_i will learn to C_0 . So, I can take or I can rewrite this as: W^T into $X_i - M_0$ whole square. Now, once again just like what we did for earlier, I can write what is inside this summation in terms of outer products. So, I can write this as $W^T X_i - M_0$ into $X_i - M_0$ transpose W . Now, the summation is over X_i . So, W can come out of this summation. So, if I pull W out of this summation, I get W^T summation X_i belongs to C_0 , $X_i - M_0$, $X_i - M_0$ transpose W .

See, M_0 is the mean of all X_i in class 0. So, if I did do this and divided by $1/M_0$; if you remember this is the maximum likely hood estimate for the co variance matrix. This is the m_l estimate for the coefficient matrix of class 0. So, I can write s_0^2 as W^T summation X_i belongs to C_0 , $X_i - M_0$, $X_i - M_0$ transpose W . This matrix off course is not at the coefficient matrix, if the coefficient matrix X_i accepts for a multiplicative factor because I need $1/M_0$ to make it an estimate of the coefficient matrix. If I do the same thing for s_1 , the only difference will be the summation will be C_1 and M_0 will become M_1 .

(Refer Slide Time: 16:44)

- Similarly, we get

$$s_1^2 = W^T \left[\sum_{X_i \in C_1} (X_i - M_1)(X_i - M_1)^T \right] W$$
- Thus we can write $s_0^2 + s_1^2 = W^T S_w W$, where

$$S_w = \sum_{X_i \in C_0} (X_i - M_0)(X_i - M_0)^T + \sum_{X_i \in C_1} (X_i - M_1)(X_i - M_1)^T$$
- S_w is also $d \times d$ matrix and is called *within class scatter matrix*.

So, similarly s_1^2 square will become W^T transpose the same matrix but, summation C_1 $X_i - M_1$ $(X_i - M_1)^T$ W . Which now means, I can write s_0^2 square plus s_1^2 square as $W^T S_w W$. Where, S_w is another symmetric matrix given by this sum of this 2 matrixes X belongs to C_0 , $X_i - M_0$, $(X_i - M_0)^T$ plus X belongs to C_1 , $X_i - M_1$, $(X_i - M_1)^T$. So, this matrix, this S_w is also the d by d matrix is called within class scatter matrix. Essentially, the first term here is propositional to the coefficient matrix of the first class of class C_0 and second term is propositional to the coefficient matrix of the class C_1 by matrix we mean the sample mean estimate of the coefficient matrix. So, S_w is called the within class scatter matrix. So, we can write s_0^2 square plus s_1^2 square as a quadratic form on S_w , $M_1 - M_0$ whole square at the quadratic form on S_w .

(Refer Slide Time: 18:03)

• Hence we can now write J as

$$J(W) = \frac{W^T S_B W}{W^T S_w W}$$

• We want to find a W that maximizes $J(W)$.

• Note that $J(W)$ is not affected by scaling of W .

• Given the data we can calculate the S_B and S_w .

• Maximizing ratio of quadratic forms is a standard optimization problem.

NPTEL course - p49102

So, now J of W becomes $W^T S_B W$ by $W^T S_w W$ is a ratio of 2 quadratic forms. So, first thing to note so, basically this is the same J as earlier. So, we just read it on a originally J W is $M^T M$ whole square by $S^T S$ whole square because both the numerator and denominator can be written as quadratic forms on some matrixes we written them like that. So, this is the J that we want to maximize. Now, is very clear that is not effect by scaling. If W replaced by $k W$, the k will be cancelled from both numerator and denominator.

So, this W is not affected by, this $J W$ is not effect by scaling of W as it should be. And it is easy enough to calculate, given the data I know how to calculate S_B , I know how to calculate S_w . So, I can calculate both the matrixes and hence given any W , I can calculate $J W$. And narration, this is very nice optimization problem. Essentially, you want given 2 matrixes as S_w , you want to find a vector capital W which maximizes the ratio of quadratic forms. Maximizes ratio of quadratic forms say every standard optimization problem and we can solve it generally easily enough.

(Refer Slide Time: 19:24)

- We need to maximize

$$J(W) = \frac{W^T S_B W}{W^T S_w W}$$

- Differentiating w.r.t. W and equating to zero, we get

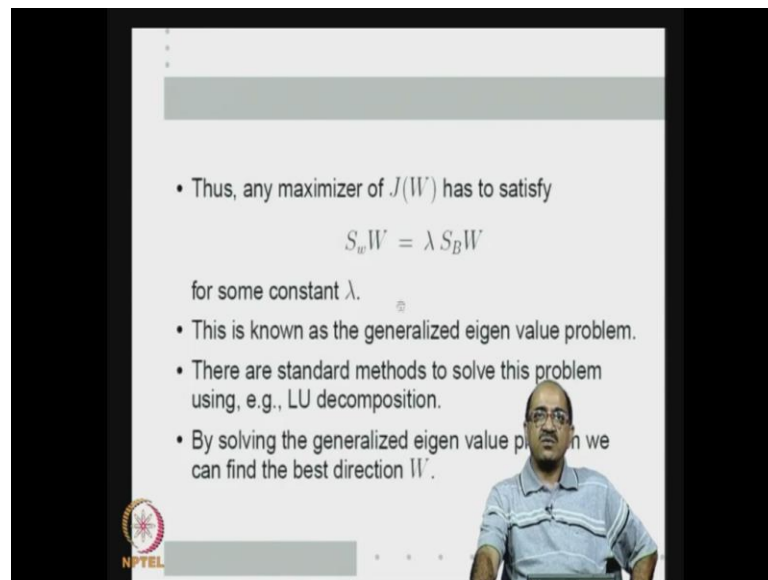

$$\frac{2S_B W}{W^T S_w W} - \frac{W^T S_B W}{(W^T S_w W)^2} 2S_w W = 0$$

- Implies, $S_B W$ is in the same direction as $S_w W$.

So, let us see how to do that. So, this is what we want to maximize. So, if you want to maximize, we differentiate or find the gradient and equate to 0. So, if I differentiate with respect to W and equate to 0, what will I get? I can first do, 1 by W transpose $S_w W$ into derivative of the numerator that will give me 2 times $S_B W$ plus the numerator W transpose $S_B W$ into derivative of 1 by W transpose $S_w W$, I can write it as minus 1 by W transpose $S_w W$ whole square into the derivative of the $S_w W$ which is 2 $S_w W$.

So, just by differentiating this and equating 0, I got this. In this, this is a quadratic form, this is denominator so, it is a scalar; this a quadratic form, that is a scalar; this is a quadratic form; that is a scalar. So, I have 1 vector here $S_B W$, another vector here $S_w W$. So, it is some constant to the vector $S_B W$ minus some constant vector $S_w W$ is equals to 0 that means, this vector and this vector are in the same direction because constant times 1 is the other. So, what this implies is that, the vector $S_B W$ is in the same direction as respective. So, the W that maximizes J is such that the matrix S_B times W is a vector in same direction of the matrix S_w times W .

(Refer Slide Time: 20:56)

The slide contains the following text:

- Thus, any maximizer of $J(W)$ has to satisfy
$$S_w W = \lambda S_B W$$
for some constant λ .
- This is known as the generalized eigen value problem.
- There are standard methods to solve this problem using, e.g., LU decomposition.
- By solving the generalized eigen value problem we can find the best direction W .

The NPTEL logo is visible in the bottom left corner of the slide.

Thus, any maximize of J has to satisfy $S_w W$ is some constant times $S_B W$. Where, λ is the constant. This is reminiscent of the Eigen value problem. In Eigen value problem you get a X is equals to λX . So, some matrix into a vector, is λ times the same vector. Here, I am not gaining the same vector but, some other matrix multiplies W . But, this is also very similar to the Eigen value problem. So, this is known as the generalized Eigen value problems.

The standard ways of solving the analyzed Eigen value problem, there are methods based on LU decomposition so on. So, once we know is a analyzed Eigen value problem; for example, your mat lab will have a very standard protein for solving this. But, anyway we will not get into the details of special methods to solve general Eigen value problems because often we can solve it easily but, right now we know that because the generalized Eigen value problem. By solving generalized Eigen value problem I can always find the best direction W .

(Refer Slide Time: 22:04)

• Often, the real symmetric matrix S_w would be invertible.

• Recall that

$$S_w = \sum_{X_i \in C_0} (X_i - M_0)(X_i - M_0)^T + \sum_{X_i \in C_1} (X_i - M_1)(X_i - M_1)^T$$

• This is a sum of large number of rank 1 matrices.

• Also each term in S_w is proportional to the sample-mean-estimate of the covariance matrix of one of the class conditional densities.

PR NPTEL course - p.10/12

But as I say often, I may not have to solve the generalized Eigen value problem. This is because the real symmetric matrix S_w is often invertible. And, why is that so? S_w is this matrix, $X_i - M_0$, $X_i - M_0$ transpose, sum door X_i belongs to C_0 ; $X_i - M_1$, $X_i - M_1$ transpose some door X_i belongs C_1 . There are atleast 2 reasons why we can suspect that this matrix is invertible. One is, we know for each i , $X_i - M_0$ into $X_i - M_0$ transpose in outer product is a rank one matrix. So, this adds lot of rank one matrix. When you add rank one matrixes suppose, I add $x_2 - M_0$ into $x_2 - M_0$ transpose to $x_1 - M_0$ into $x_1 - M_0$ transpose. If x_1 and x_2 are linearly independent then, this becomes a rank 2 matrix.

So, if I keep adding many rank one matrixes because the rank one at most go by 1 but, if we should the sufficiently many. So, the first reason is that this is a sum of a large number of rank one matrixes. If the number is large and X_i are in general position, it is unlikely that all the X_i will be in some lower dimensional subspace. Since, if all the X_i are not in lower dimensional subspace then, adding all these rank one matrixes should give me a full rank matrix. Normally, the number of samples is much larger than the dimension d and hence, adding that many rank one matrix should give me a full rank matrix. Another reason, why we think why often this as a invertible is that as you seen, each term in this is a good estimate especially the data is large or prepositional to a good estimate of the covariance matrix X_i and the covariance matrix will be invertible. So, by

in both ways we accept S_w to be invertible. Suppose, S_w is invertible then, it is very much easier to solve for d .

(Refer Slide Time: 24:18)

• If S_w is invertible, then we can write

$$W = S_w^{-1} S_B W$$

• We have

$$S_B W = (M_1 - M_0)(M_1 - M_0)^T W = k(M_1 - M_0)$$

where k is some constant. (note $k = (m_1 - m_0)$)

• Now we get (since scale factor in W is not relevant)

$$W = S_w^{-1}(M_1 - M_0)$$

Let us say, S_w is invertible. So, we have seen in the W has to satisfy S_w into W is equals to $\lambda S_B W$. So, if this matrix is invertible, I can multiply by S_w inverse. So, I get an equation for W or atleast relation W is equals to something. So, let us look at that relation.

Suppose, S_w is invertible then, W can be written as S_w inverse S_B times W . There is There has to be λ here, I omitted the λ because ultimately constant factor is do not make much difference but, any way there is a λ here. Let us not worry about that right now. This looks like off course an Eigen value problem. Putting a λ here, it is the Eigen value of S_w inverse S_B . But, we do not even have to look at the Eigen values because $S_B W$, what is S_B ? M_1 minus M_0 , M_1 minus M_0 transpose into W . We know M_1 minus M_0 transpose W is nothing but little M_1 minus little M_0 which is scalar. So, this is some scalar k times M_1 minus M_0 as I wrote here, k is equals to M_1 minus little M_1 minus M_0 .

So, $S_B W$ is a vector is propositional to M_1 minus M_0 . So, I can replace $S_B W$ by some constant times M_1 minus M_0 . So, which gives me W is S_w inverse M_1 minus M_0 . There are so many constants; there is a λ here, there is a k here. So, ultimately there will be some constant times S_w inverse M_1 minus M_0 . But, as I said constant do

not make difference in a linear classifier. Right. We can accordingly k W on b to anything that we want.

So, essentially we can find the W x surface scale factor to S w inverse M 1 minus M 0 and I do not want to worry about the scale factor, I can take this to be W because I am in a linear classifier context. So, this is the W that I can use as the fisher linear discriminant, if the matrix S w transpose to be invertible which as we just now said very often that would be the case.

(Refer Slide Time: 26:28)

Obtaining Fisher Linear Discriminant

- We can sum-up the process as follows.
- Given the training data, we first form the scatter matrix S_w and also calculate the means M_0 and M_1 .
- If S_w is invertible, we calculate W by $W = S_w^{-1}(M_1 - M_0)$.
- Even if S_w is not invertible, there are techniques to find the maximizer of $J(W)$ by solving the generalized eigen value problem.
- Thus we can find the best direction W .

NPTL

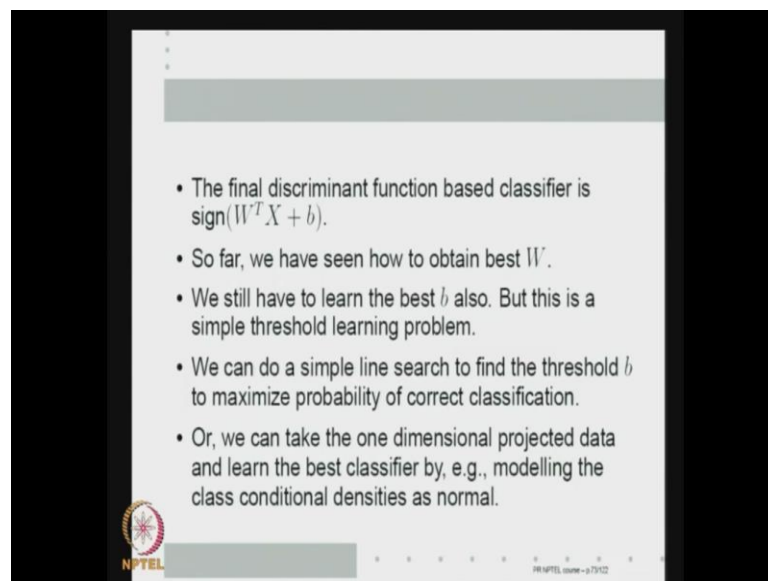

So, let us sum-up how we obtain fisher linear discriminant. With given the data, given the data, we first form the scatter matrix S_w and also calculate the mean M_0 and M_1 . Once the within class scatter matrix S_w is invertible, I can directly find W . As S_w is invertible, I can calculate W by S_w inverse M_1 minus M_0 , that is the fisher linear discriminant direction. Or it is normal to the hyper plane classifier given by the fisher linear discriminant.

Just for completeness let us remember that, even if S_w is not invertible there are techniques to find maximizes as a W by solving some generalized Eigen value problem. There are some techniques, even the generalized Eigen value problem. If S_w is not invertible, there are some issues. I will just show that, so that you will appreciate that there are some issues that means just go back to.

If S_w is rank deficient, what it would not mean is there can be some W at which $W^T S_w W$ goes to 0. Right. Thus, there would be some W for which this will be infinite but, thus not the W we want. So, we have to define this little more carefully. But, it does not matter there are techniques to take care of it. So, we will just we would not go there but, will just remember that.

If S_w is invertible, W is given by this. Even, otherwise one can find a maximize by solving some generalized Eigen value problem. So, that is how we obtain the best direction W ; very often this is what is no given as the fisher linear discriminant, as said in most pattern recognition problems S_w would be invertible. So, this is the fisher linear discriminant. But, obviously we have found only the best direction W . We have not yet found a classifier. Right.

(Refer Slide Time: 28:36)

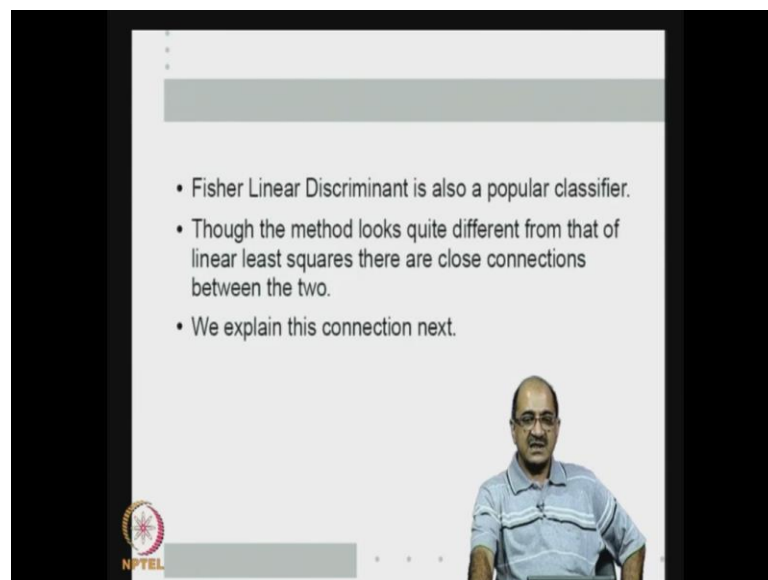

Let us remember that a discriminant based classifier is $\text{sign}(W^T X + b)$. So, I have to find the b also. Right. All that we have done so far is how to find the best W . And have been found best W , to convert it to a classifier I still have to find W . But, this is a must simple of problem right. We have to tell on the best b but, this simple problem just learning a threshold. We are saying this is the best direction now, we have one dimensional data and I want the best threshold. So, now given one dimensional data and class labels, I just want a threshold bayes classifiers. I am asking which threshold is good, there are many methods.

For example, we considered ROC, how we can experimentally calculate ROC and come to a threshold; that is one thing. We can do we can do any that kind of such for a threshold. We essentially have to along W , we keep putting the threshold at various points and keep asking is my accuracy and the training data improving. I need only one threshold. So, I will start from some end of some point and keep moving, just like a line search in the optimization problem. So, we can do a simple line search to find the best threshold, to maximize the probability of a correct classification and the training data.

Or, what we do is, the projected one dimensional data z_i that is, what we have with class labels. We can simply take it as a one dimensional pattern recognition problem and is very easy to solve one dimensional pattern recognition problem. For example, we can take the class conditional density to be normal, estimate the associated normal densities very easy to do for one dimensional as you have seen. And then, take the classifiers based on the estimated densities. This is also often done. So, in whichever way we do that gives us the final fisher linear discriminant. So, this is how I would obtain the fisher linear discriminant.

(Refer Slide Time: 30:37)

Officially, a discriminant is also a popular classifier, just like the least squares. Now, the way we derived fisher linear discriminant it looks quite different from the least squares method. As I had told you, a fisher linear discriminant came from also, came from statistic but, not it came from different direction.

So, essentially linear least squares and Fisher linear discriminant evolved historically as different algorithms. However, how different it may look, there are close connections. As the matter of fact we can think of Fisher linear discriminant as a special case of linear least squares. The reason we did not start there is that because historical is important, it is very often used in applications and is nice to know another way of formulating what is a good linear classifier. But, having said all that, one can actually mathematically show the equivalence of linear least squares and Fisher discriminant in a very specialized sense. What is specialized sense; is the following.

(Refer Slide Time: 31:48)

- Given the original training data $\{(X_i, y_i)\}$ we form new training data $\{(X_i, y'_i)\}$ as follows.
- We take $y'_i = n/n_0$ if $y_i = 0$ and $y'_i = -n/n_1$ if $y_i = 1$.
- We now treat this as a data for a regression problem and learn a model $\hat{y} = W^T X + b$ using linear least squares.
- It can be shown that the least squares solution for W would be same as that of FLD.
- Thus FLD can be viewed as a special case of linear least squares.

We start with some data X_i, y_i . This is our given data X_i is in $\mathbb{R}^d$, y_i is 0 or 1; this is our classification data. Given this data suppose, we form some new training data where, X_i are same but, y_i 's change it to y_i prime.

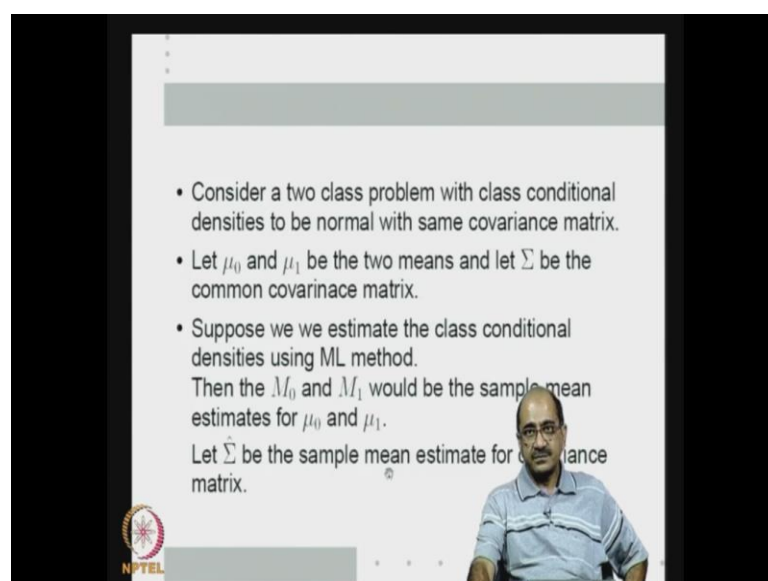

How do I form the new y_i primes? Originally, y_i 's are 0 and 1. So, if y_i is 0 that is, X_i is coming from class 0, I take y_i prime to be n/n_0 . So, I am just changing the targets for all class 0 patterns, the correct value to predict is n/n_0 . Where, n is the total number of samples and n_0 is the samples of class 0. On the other hand if y_i happened to be 1, I take y_i prime to be minus n/n_1 . So, now I got new data X_i, y_i prime where, y_i prime take some real numbers not 0 or 1 because n/n_0 and minus n/n_1 are some real numbers. Even though we take some real numbers we will think of y_i prime as some generic real numbers. Then, we can treat this X_i, y_i prime data as a regression

problem. X_i is an $r \times d$, y_i prime are a naught; I want a predictor, I want a linear predictor where, I have $W^T X_i + b$.

Simply, viewing X_i, y_i as some data for a regression problem, I can certainly use least squares to find a linear predictor. What I have is $W^T X_i + b$. Using the outstanding linear least square method that you have done in the last couple of lectures. One can show algebraically the algebra is a little tedious but it is there in one of the prescribed text book namely, Bishop's book. But, it can be shown through somewhat long variant algebra that, if I do that, if I take this data recoded X_i, y_i and then, think of this as a data for regression problem and then, find a linear regression. Then, one can show that the least square solution W that I obtain for fitting this model to this changed data will be exactly same as the W that we get out of Fisher linear discriminant.

I am not prove this I am not proving this, as I said the algebra is tedious and it possibly does not add much score through the algebra, it is also there in Bishop's book. But, it should know that, it can be shown that the least square solution have obtained here would be this, would be same as the Fisher linear discriminant. Thus, one can show or one can see that Fisher linear discriminant can be viewed as the special case linear least squares. So, it is not really different from linear least square but, at the same it gives you another very important useful idea of how one looks at what is a good linear classifier.

(Refer Slide Time: 34:32)

- Consider a two class problem with class conditional densities to be normal with same covariance matrix.
- Let μ_0 and μ_1 be the two means and let Σ be the common covariance matrix.
- Suppose we estimate the class conditional densities using ML method. Then the M_0 and M_1 would be the sample mean estimates for μ_0 and μ_1 . Let $\hat{\Sigma}$ be the sample mean estimate for covariance matrix.

There is other ways of looking at how good fisher linear discriminant is. For example, we take simplest 2 class problem; let us say we have a 2 class problem with both the class conditional densities to be normal unless they say they have the same covariance matrix. Why same covariance matrix? If the 2 class of the same covariance matrix we know that the based optimal classifier is a linear classifier. Right.

So, now one can ask, will fisher linear discriminant give me the optimal linear classifier because fisher linear discriminant can give me only linear classifiers. We can only ask whether will give the optimal classifiers when the optimal classifier itself is a linear. So, let us take a case class conditional density is normal with same covariance matrix and we know that the based optimal is a linear classifier and will show that fisher linear discriminant will give me the same classifier as the based classifier. So, let us say μ_0 and μ_1 are the 2 means of the classifiers classes and because the covariance matrix is same, there is only 1 sigma for both classes. Thus, sigma is the common covariance matrix. Suppose, given this data if we want to actually implement bayes classifiers we would estimate class conditional densities; let us say using maximum likely hood method. If we give maximum likely hood method, we know μ_0 and μ_1 will be estimated in sample means. Similarly, a similar sample mean estimate exists for the covariance matrix.

So, then we know that M_0 and M_1 would be the sample mean estimate is for μ_0 that is how we obtain. M_0 is $\frac{1}{N} \sum_{i=1}^N X_i$ so, the sample mean estimated for μ_0 similarly, M_1 . So, I would have obtained the same M_0 , M_1 as the sample mean estimate for μ_0 and μ_1 had a try to do this estimation of class conditional densities under maximum likely hood. Similarly, I would I would have got some $\hat{\sigma}$ as the estimate with the covariance matrix.

(Refer Slide Time: 36:28)

• Then the Bayes classifier, implemented with estimated class conditional densities, would be a linear classifier $\text{sign}(W^T X + b)$ where W is given by

$$W = \hat{\Sigma}^{-1}(M_1 - M_0)$$

• It is easily seen that this would be essentially the same as the W given by FLD.

The slide features a speaker in the bottom right corner and an NPTEL logo in the bottom left corner.

Then, what will be the bayes classifiers, we implement with this estimated quantities. If you still remember the bayes classifiers that we derived for common covariance matrix Σ . It is a linear classifier $W^T X + b$ where, the W is given by $\Sigma^{-1}(\mu_1 - \mu_0)$. So, what I would have implemented is $\hat{\Sigma}^{-1}(M_1 - M_0)$. Now, we know that this has to be same as the FLD because we know that the Σ is inverse that comes there is like covariance matrix. So, very very quickly will show that this W would be same as the W given by the fisher linear discriminant.

(Refer Slide Time: 37:12)

• Recall that the matrix S_w is defined by

$$S_w = \sum_{X_i \in C_0} (X_i - M_0)(X_i - M_0)^T + \sum_{X_i \in C_1} (X_i - M_1)(X_i - M_1)^T$$

Since the two classes have the same covariance matrix, each of the two terms above would be proportional to sample mean estimator for Σ .

• Thus, S_w is proportional to sample mean estimator of covariance matrix.

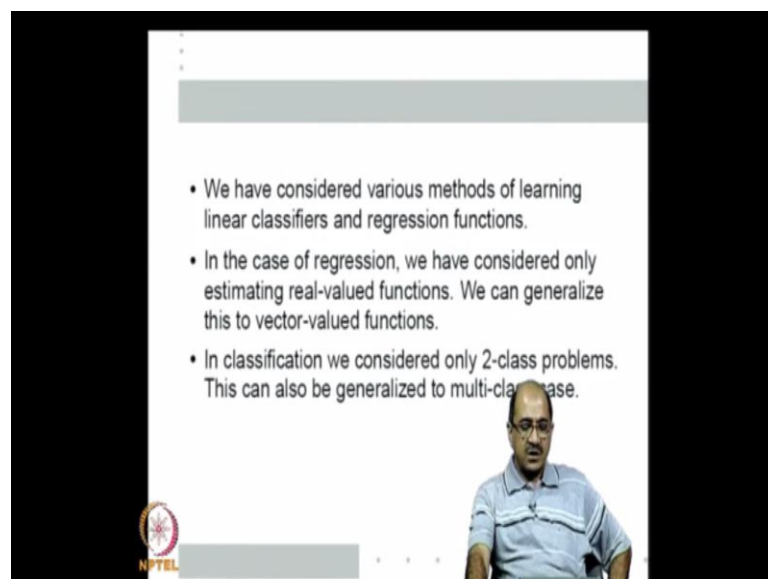

• Thus, the FLD given by $W = S_w^{-1}(M_1 - M_0)$ would be essentially same as the Bayes optimal classifier.

The slide features a speaker in the bottom right corner and an NPTEL logo in the bottom left corner.

Coming back; this is the S_w matrix. Because both classes are having the same covariance matrix, I could estimate the covariance matrix either from class 1 or from class 0. So, if I estimate this from class 0, that estimate would be proportional to this accept for a proportional constant. Simply, if I estimate it from class 1 it will be proportional to this accept proportional constant. And the classes are the same covariance matrix; each of the 2 terms above would be proportional with the same sample mean estimated. Right. So, the first term will be some a times σ^2 and the second term will be some b times σ^2 . So, essentially S_w will be proportional to σ^2 .

So, since S_w is proportional to the sample mean estimate for σ^2 , we know that the Fisher linear discriminant is given by $S_w^{-1}(M_1 - M_0)$ is same as the Bayes optimal classifiers. So, Fisher linear discriminant is an interesting classifiers because at least in this kind of cases it gives you the Bayes optimal classifiers. So, it has a variant testing geometric interpretation namely, finding a direction along which classes are well separated. That is that is in itself is a nice interesting geometric interpretation. In addition, as you seen it can be viewed as a special case of least squares. And also, you know in this in the cases that Bayes optimal is linear, I am getting at least in the normal class conditional densities case. Fisher linear discriminant gives me the same classifier as the Bayes optimal. So, that is the story of the Fisher linear discriminant.

(Refer Slide Time: 39:06)

The video frame shows a presentation slide with a white background and a black border. The slide contains three bullet points:

- We have considered various methods of learning linear classifiers and regression functions.
- In the case of regression, we have considered only estimating real-valued functions. We can generalize this to vector-valued functions.
- In classification we considered only 2-class problems. This can also be generalized to multi-class case.

In the bottom right corner of the slide, there is a small inset video of a man with glasses and a light blue shirt, who appears to be the speaker. In the bottom left corner of the slide, there is a small logo with the text "NPTEL" below it.

So, to move on; we consider various methods of learning linear classifiers and linear regression models starting with perceptron and then, we spent a lot of time on linear least squares methods and now, fisher linear discriminant. But, most of the time we are restricting ourselves when we doing regression we are talking of targets being in $\mathbb{R}$ in the regression case where we assume the training data as X_i, y_i where, y_i belongs to $\mathbb{R}$. What it means is, we are only estimating the real valued functions.

So, one generalization that we may want to do is to generalize this to vector valued functions. Right. Similarly, whenever we consider classifiers the classification problem we always restrict our self to do class problems so we have to generalize this to multi class problem. These are the 2 issues still left. So, in this class will atleast look at the issues involved and will tell you what the things are and pretty much that is all the least for multi class classifier. We may just briefly touch upon it next class and leave it at that. So, let us do it one by one.

(Refer Slide Time: 40:13)

- First consider estimating vector-valued functions.
- Now the training data is $\{(X_i, y_i), i = 1, \dots, n\}$ where $X_i \in \mathbb{R}^d$ and $y_i = (y_i^1, \dots, y_i^m) \in \mathbb{R}^m$.
- For any given X we want to predict the target $y = (y^1, \dots, y^m)$.
- Thus we want to learn $W_j, b_j, j = 1, \dots, m$ so that

$$\hat{y}^j = W_j^T X + b_j, j = 1, \dots, m$$
- We can obtain these by simply solving m number of linear least squares regression problems.

So, let us first look at the regression problem. First consider estimating vector-valued functions. What does vector-valued function mean? Now, my training data is given by X_i, y_i . As earlier, X_i is a feature vector it belongs to $\mathbb{R}^d$, y_i is the target. Now, because I am learning vector value function let us say the function map from $\mathbb{R}^d$ to $\mathbb{R}^m$. So, y_i will be m vector. I am sorry this should not be $\mathbb{R}^d$, this should be $\mathbb{R}^m$. I am sorry about

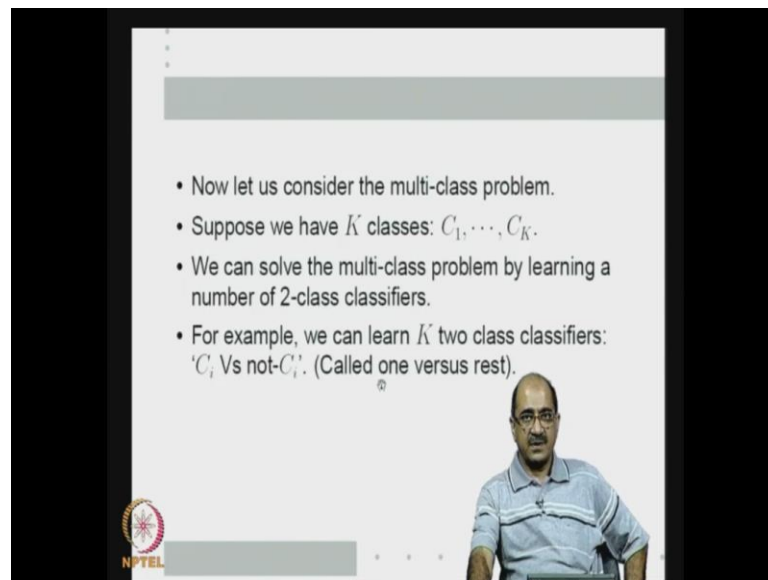

that. But, anyway y is a m vector. So, because we already put i for denoting the i 'th sample.

Let us put, let us denote the components of y_i by y_{i1}, y_{i2} upto y_{im} . So, the main difference in the vector value case is that y_i is now a vector of some m components for some arbitrary value of m . So, given any X , we want a model that can predict the target which is a m vector. So, given any X we want to predict y which is actually an m vector given whose components are y_1 to y_n . And we want to do it using our basic linear methods. So, what it means is that, we want to learn m W 's and b 's such that, the j 'th component can be predicted as some a fine function that is, $W_{\cdot j}^T X + b_j$. So, essentially the problem falls down to find m vectors W_j and m scalars b_j .

So, that is a good model, my good model my prediction model would be the j the estimate of the j 'th component in the target $\hat{y}_j$ is $W_{\cdot j}^T X + b_j$. What is mean? If I just take this data and split it into many data's $X^{(1)}, y^{(1)}$ is 1 data set, $X^{(2)}, y^{(2)}$ is another data set, $X^{(3)}, y^{(3)}$ is another data set and so on. For each data set I find a standard least squares methods. Right. So, this learning a vector valued function is no different from simply solving m number of linear least squares regression problems.

So, simply by learning running m linear least squares regression problems, we can solve the vector vector case. Of course, we can all put it into a better formulism. We can actually put all these W_j 's as columns of a W matrix in d right a the entire least squares solution in a vector matrix notation. But, except for some complication notation, there is nothing really conceptually linear over here because we are simply effectively running m number of linear least square regression problems. So, which means in principle, we know how to solve the ah linear model problem even if we have to learn a target function which is vector value.

(Refer Slide Time: 43:22)

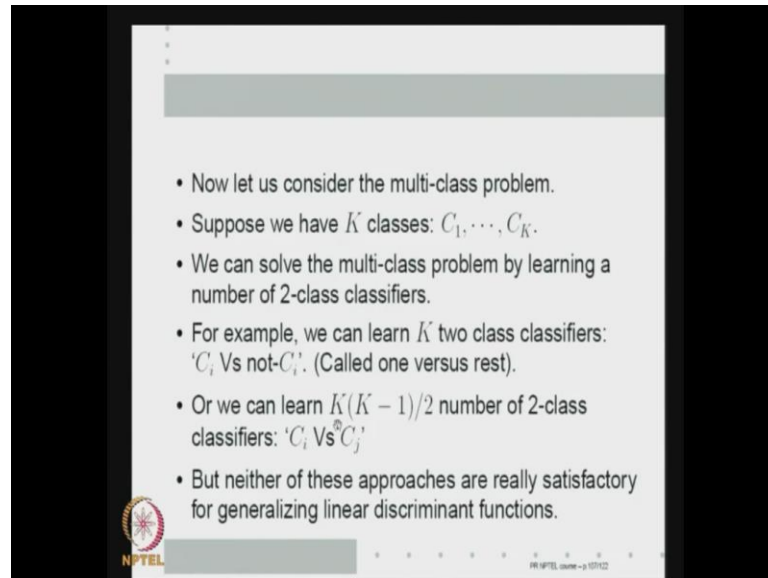

Now, let us come to the multi class problem. If i know so far we know many methods for learning 2 class problems. So, If i know how to learn 2 class problems, can i find? Can i use the 2 lane multi class problem? The issue is just a little more complicated here, we have earlier considered this. So, let us say we have k classes C_1, C_2, C_K . So, will come to decide how the data will be. For knowledge let us assume that we get X_i, y_i then, y_i takes any any any value between 1 and k.

Note that earlier we always been looking at our classes some C_0, C_1 so on. At this time we look at a C_1, C_2, C_K . Now, as i said some time ago essentially 2 class problem is the more fundamental problem because we can solve multi class problems simply by if you know how to solve 2 class problem. So, we can in principle solve number of 2 class problems to solve a multi class problem. There are atleast 2 very generic techniques of a learnig in a multi class problem using 2 class methods. One is that i can learn K 2 class classifiers where, K is the number of classes as follows. I learn C_i verses not- C_i .

So, the i'th classifier I learn is learning to classifier C_i verses not- C_i . What you mean by C_i verses not- C_i ? I have the data, a training data of the K class K's so, I take all the data, all the X_i that belongs to a particular classes say C_i or say all data that belongs to C_1 as 1 class all the rest of the data as another class. Then, I solve a 2 class problem whose objective is to say given an X is it is in C_1 or is not in C_1 . Similarly, is it in C_2 or not in C_2 . So, I learn key a number of 2 class classifiers, each classiffier is learnig to

distinguish between C_i or not- C_i . This approach is often called one versus rest and is a very standard approach in learning multi class case. Especially, in when you one one does all in a classifier very often one goes for on verses rest approach.

(Refer Slide Time: 46:02)

Another way of doing it is inster learning K, I learn K C 2 number of 2 class clasifiers. Now, for every distinct pair i and j I am learning 1 classifier to distinguish here C_i from C_j . The main of course, I am learning more number of classifiers here. Why should I learn more number of clasifiers, why cant i use the previous method where I have to learn only K classes? One problem with this C_i verses not- C_i learning could be that for this problem, the effective training set could be very (()) . Let us say I have 100 classes and I have let us say 50 examples of each class making a total of 5000 examples.

Now, when I want to do C_1 verses not- C_1 , I have only 50 examples of C_1 whereas, 4950 examples of not- C_1 . fine. Then, if one of the classes has much less much less represent the training set then the another 2 class problem. Predominantly, all traning data belongs to to 1 class, that is very diffucult to learn the classifier. For example, in this case if i have 50 of 1 class and 5000 minus 50 of the other class. Then, a classifier always says not- C_1 has only a error rate of 50 by 5000 on the traning data which is very small right. So, stupid classifiers can have very low error on the training set and that always makes it difficult. Often, what one does is when 1 class as too many samples then, you resample from there. So, out of this 4050 I may be I take some 50 or 100

randomly selected samples and use that to do C_i versus not- C_i . But, when I do that may be that does not represent all the other not C_1 not- C_1 classes.

So, if the number of classes is very large then, one versus rest can be difficult. Because the training data subset will be very sparse for the resulting 2 class problems. If I have only 3 or 4 classes then it may not be so bad. But, if I have hundred or 200 class 100 classes or 50 classes then learning C_i versus not- C_i could be a sparse data set problem and I have to properly balance the data set. It is in those cases that learning C_i versus C_j classifiers could be because if essentially when I have got K class problem and I have training data, one expects that all class all classes are represented about equal measure. So, for a 2 class problem C_i versus C_j , I will have roughly equal number of example for both classes there is no sparse training data distribution.

So, this is a little more easier, is more stable 2 class classifier learning and that the reason even though I am learning more number of classifiers, I may want to do this. So, these are essentially 2 ways of using, there are others but, these are the 2 main ways of using an algorithm that can learn a 2 class classifier to classify K classes. But, however there are issues with both of these. Right. I will we will We will see look at some problem, there is not to say that there are not followed.

But, there are pitfalls with both the approaches in as much as any set of such classifiers, this set of K classifiers or this set K into K minus 1 by 2 classifiers do not make a perfect, a well defined classifiers. Perfect is wrong word to use because we are not saying it has to have 0 error or anything like that. But, at least it should be a well defined classifier. What do you mean by this? A classifier is a black box to which if I give an X . There is no doubt in the classifiers mind as to what class X should be goin because this is an algorithm, it has to be an algorithm. Whether, it is right or wrong is a different issue but, something to be call a classifier at least structurally, given an X it should be assigned to one unique class.

But, if I learn this many 2 class classifiers or this many 2 class classifier, together they do not really define a very a proper classifier in this sense. Thus, what will see next that neither this approaches are really satisfactory generalizing the linear discriminant function to multiple classes. So, before I will show you some examples of why this happens and tell you how we can solve this.

But, before I go there I spent a lot of time telling you about this 2 ways of dealing with multi class problems because inspite of the problems I am going to tell you, sometimes people use this approach for solving multi class problem. But, we should still know what the pit falls in the approach are.

(Refer Slide Time: 51:18)

• Suppose we try 'one versus rest' approach. Then there may be regions of feature space where classification is ambiguous.

So, let us first consider one versus rest approach. The problem is that there are regions of feature space where, the classification is ambiguous. Right. Let us say, this is the linear classifier that separates class C_1 on one side and not C_1 on the other side. Let us say this is a linear classifier that separates class C_2 on one side and not C_2 on the other side. This is the region 3 where, it is class 3 as it should be not C_1 , not C_2 . But, there will be region like this where, this classifier will say C_1 and that classifier will say C_2 , maybe my third classifier will say not C_3 . That is all right. But, what should I do here; because if I take any X here one classifier says C_1 , other classifier says C_2 , my third classifier says not C_3 . So, that is okay, not C_3 is fine. But, is it C_1 or C_2 or no way of knowing. So, this does not even define a proper function that maps every feature vector to a class. Right.

(Refer Slide Time: 52:21)

• Similar problem exists when we try ' C_i Vs C_j ' approach

The same this is to even, if you use C_i verses C_j approach. Once again here is an example. So, in 3 class case. So, this is a C_1 verses C_2 line, Right. That is, a C_1 verses C_3 line, this is C_2 verses C_3 line. In the centre triangle where, I put the question marks if I take any x ; one classifier will say C_1 , another classifier will say C_2 , the third classifier will say C_3 . A perfect disagreement between the 3 classifiers. What should I assign it as the class label?

So, there is always this issue when I have that many 2 class classifiers. If the responses given them are consistent then, given any x , I can decide on the class label for that x . But, there will always be the regions in the feature space like this. Where, the responses are inconsistent and one does not have any simple solution of how to put together all those responses into a perfect or into a proper class labels. This is the problem of generalizing 2 multiple classes.

(Refer Slide Time: 53:27)

- A better way to formulate a linear discriminant function based classifier for the multi-class case is as follows.
- We will have K functions, g_s , $s = 1, \dots, K$, given by
$$g_s(X) = W_s^T X + b_s$$
- Now the classifier would assign class C_j to X if
$$g_j(X) \geq g_s(X), \forall s$$
- In the above we would have a fixed (may be arbitrary) rule for breaking ties.
- Recall that this is the way we generalized Bayes classifier to multi-class case.

Of course, there is a better way of formulating this. We have seen this when we considered multi class bayes clasification for minimizing this. The same thing is to do in the linear discriminant functions. Essentially, the way to generalize 2 multiple classes is will have K functions, I represent them as g_s , s going from 1 to k and each function is a standard linear function. That is a fine function rather, $g_j(X)$ is $W_s^T X + b_s$. Right.

Now, I define a way of making this into a classifier for all such functions. Now, once I have all these functions, if i if you give me an X , I will assign X to class C_j , if $g_j(X)$ is greater than $g_s(X)$ for all s . So, I calculate the value of X for each of this functions and which every function has the maximum value of X at that point X , I will assign X to that class. of course, this is not at complete because there will be ties. Right. So, there might be say $g_1(X)$ and $g_2(X)$ might have the same value and that is bigger than the value of $g_j(X)$ for all other j . Now, should I put X in class 1 or class 2. But, once we come this for we can have a very simple and arbitrary rule for breaking ties. For example, I can say that if the maximum is attained at more than 1 j then, I will put it to the j to the least j .

So, if $g_1(X)$ and $g_2(X)$ are the 2 maximum of function values for x then, I will put it in one. Right. So, I can have any arbitrary but fixed rule for breaking ties so that it becomes a proper function. Given any X it uniquely defines a class label. So, essentially this is

how one would like to generalize linear discriminant functions to multiple classes. Recall that, this is the we have generalize the bayes classifiers.

(Refer Slide Time: 55:28)

Now, to learn a linear classifier for K -class case, we need to learn all the K functions g_s . The best way to do this is to use or vector valued idea of regression functions. So, what we do is, we make the class label to be a vector of K components. What is that mean? If X_i belongs to C_j then, in the training data the class label y_i instead, of simply taking value j , it actually will be a K vector with the j^{th} component 1 and all others 0.

Now, y_i will be K vector now. And to denote j^{th} class j , I put 1 in the j^{th} component and 0 will be. So, each y_i will be a unique one of the co-ordinate vectors. So, we seen similar coding when we consider this K random variable as M l estimation. So, the same codind we can use to make the class labels K vectors. Now, learning K functions is same as a linear regression with vector valued targets. I am given X_i, y_i ; y_i are vectors. I want to learn a linear function. So, I can learn K functions using linear regression with vector value targets. So, this is one standard way in which linear (()) analysis can be extended to multiple classes. There are of course some slighly different ways and this by itself does not tell you how y can generalize logistic regresion or fisher linear discriminant because they there the structure of landing is slightly different there.

But, similar ideas can be used for generalizing logistic regresion fisher linear discriminant also. So, with the next class we will just briefly look at how to generalize

logistic regression to K classes. And then, we will step back we since some algorithms now for learning a classifiers. We will just take a look at all the algorithms and then, take a step back and ask, is there some therotical ways in which we can say whether one classifier is good or not good; how do we decide whether a classifier is optimal or good; is there a a statistical way of defining the goal of learning in learning a clasifier. So, we will do a better statistical learning theory and then, we returned to learning non-linear classifiers. Now, that we finished all linear clasifiers, we will step back to do some statical learning theory and then, come back and do the non-linear classifiers.

Thank you.
