**Adaptive Step Size Runge Kutta Scheme**

So far we have been looking at numerical solutions of differential equations of the form  $y' = f(x, y)$  with some boundary conditions specified at  $x = x_0$  in the beginning of the interval and we looked at 3 different methods actually, 4 different methods, 2 of them being on the Runge Kutta scheme and in these methods, we wrote  $y$  at  $x + h$  as  $y$  of  $x$  plus  $f$  into that is  $y'$  evaluated at  $x, y$  into  $h$ .

So we wrote these methods and so that is 1 method which we said Euler's scheme and then we can go starting from  $x_0$  to the other end of the interval which you are interested in another method which we looked at was to evaluate what is called a predictor which at  $x + h$  from this scheme and then use a corrector step to get the  $y$ , the correct value as  $f$  of  $x + h, y$  and the derivative evaluated at  $x + h$  and  $y_0$  at  $x + h$  divided by 2.

(Refer Slide time: 05:16)

$$\begin{aligned}
 y' &= f(x, y) \\
 y(x_0) & \\
 y(x+h) &= y(x) + f(x, y)h \\
 y^0(x+h) &= y(x) + f(x, y)h \\
 y(x+h) &= y(x) + \frac{1}{2}(f(x, y) + f(x+h, y_0+h)) \\
 y(x+h) &= y(x) + \frac{1}{6}(k_1 + 4k_2 + k_3) \\
 k_1 &= hf(x, y) \quad k_2 = hf(x + \frac{1}{2}h, y + \frac{1}{2}k_1) \\
 k_3 &= hf(x + h, y + k_2) \quad k_4 = hf(x + h, y + k_3)
 \end{aligned}$$

So that is another scheme which we looked at and we said that we could do this iteratively and the predictor corrector scheme to get better accuracy and the second order Runge Kutta method which we looked at was exactly this 1. So this is predictor corrector and second orders Runge Kutta in which we evaluate the derivative at 2 points one at the beginning of the interval and 1 at end of the interval with a predicted value of  $y$ , predicted

value of the function and then taking the mean of that derivative and in the scheme where we looked at the 4th order Runge Kutta.

So then we wrote here  $y$  at  $x$  plus  $h$  as  $y$  at  $x$  plus  $1$  by  $6$  times  $k_1$  plus  $2k_2$  plus  $2k_3$  plus  $k_4$  and  $k_1$  was  $f$  of  $xy$  and so  $k_1$  was  $f$  evaluated at  $x$  and  $y$  and  $k_2$ , into  $h$  that is what we wrote that as, so  $k_1$  was  $h$  times  $f$  of  $xy$  and  $k_2$  was  $h$  times  $f$  evaluated at  $x$  plus  $h$  by  $2$  and  $y$  plus  $k_1$  and similarly  $k_3$  was  $h$  times  $f$  evaluated at  $x$  plus  $h$  by  $2$  and  $y$  plus  $k_2$  and then  $k_4$  was  $h$  times,  $h$  into function evaluated at  $x$  plus  $h$ , derivative evaluated at  $x$  plus  $h$  now and  $y$  plus  $k_3$ . So this is the scheme which we have learnt so far.

So we want to solve equations of this type first order differential equation with the boundary conditions specified at the beginning that is initial value problem and we looked at the Euler's scheme the predictor corrector scheme and so this is basically the predictor corrector scheme or the second order Runge Kutta scheme and then a 4th order Runge Kutta scheme. So this is what we have so far looked at, now the question would be that if I want to solve differential equations of higher order, higher order differential equations and then what would I do. So how do I proceed in the case if I have to solve a higher order differential equation that is if I had to take differential equations of the form, let us say  $y$  double prime is equal to some function of  $xy$  and  $y$  prime.

So that is now right hand side is a function of  $xy$  and the first derivative and this is the second derivative  $y$  double prime is second let us say this is a equation of order 2. So let us say I want to evaluate I want to solve an equation of this form between some interval  $x$  going from  $x_0$  to  $x_1$  again we are only interested in the initial value problems that is we could say that  $y$  is specified at  $x$  equal to  $x_0$  and  $y$  prime is specified at  $x$  equal to  $x_0$ .

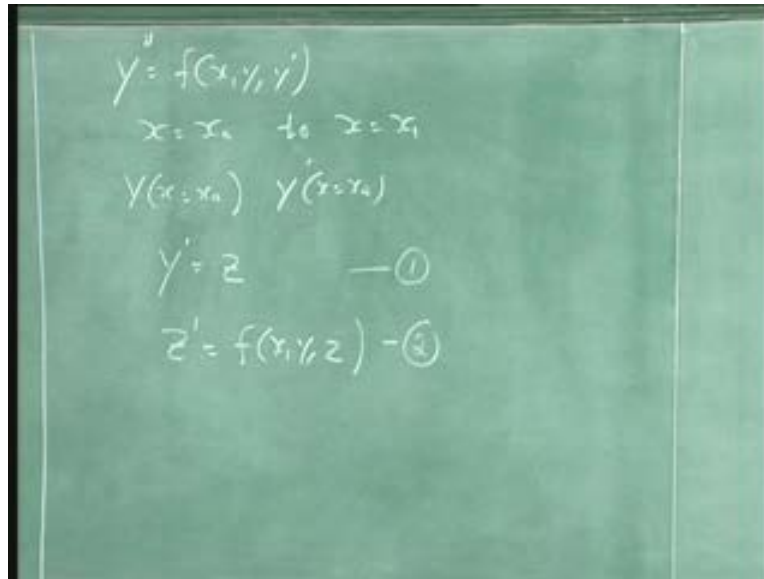

So now this is a second order differential equation, so we need 2 boundary conditions and both boundary conditions are specified at the initial value that is called an initial value problem. Of course, you could have problems in which 1 condition is specified at the initial case  $x$  equal to  $x_0$  and the other 1 is specified at the other boundary.

So then that will become a boundary value problem, we can use the method which we learned here to solve problems of that type we will discuss that at the end of this section. Okay so for the time being let us concentrated on this issue that is how to solve an equation of this form with the boundary condition specified at the initial value that is second order differential equation with boundary condition specified at the initial value using 1 of those schemes which we have learnt.

So we would use a Runge Kutta scheme for solving this equation, so what we do is we split this into 2 first order equations that is we would write  $y$  prime is equal to  $z$  and then say  $y$  double prime. So now  $y$  double prime that is  $z$  prime, so that is  $z$  prime is equal to  $f$  of  $x y z$ . So that is the that should be our equation. So now we have 2 equations instead of 1 second order equation we have 2 first order equations and now we have boundary conditions for this as  $y$  at  $x$  equal to  $x_0$  and then we have boundary condition for this which is  $z$  at  $x$  equal to  $x_0$ .

So we have boundary condition each 1 boundary condition for each of them and then you can solve these equations. Okay now that is the scheme which you would be following here.

(Refer Slide time: 08:50)

$$y'' = f(x, y, y')$$

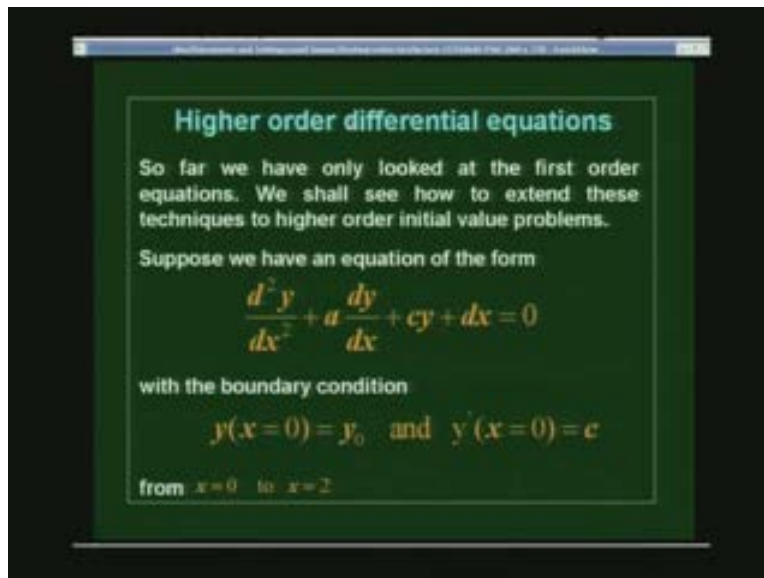

$$x = x_0 \text{ to } x = x_1$$

$$y(x_0) = y_0 \quad y'(x_1) = z_1$$

$$y' = z \quad \text{--- (1)}$$

$$z' = f(x, y, z) \quad \text{--- (2)}$$

(Refer Slide time: 08:52)

**Higher order differential equations**

So far we have only looked at the first order equations. We shall see how to extend these techniques to higher order initial value problems.

Suppose we have an equation of the form

$$\frac{d^2 y}{dx^2} + a \frac{dy}{dx} + cy + dx = 0$$

with the boundary condition

$$y(x=0) = y_0 \quad \text{and} \quad y'(x=1) = c$$

from  $x=0$  to  $x=1$

So I will summarize that here we want to let us say for example, here is an example of 1 differential equation of that form. So you have a second order differential equation, so it is d square y by dx square plus a dy by dx plus cy plus d into x is equal to 0. So now we have a differential equation of this form.

So this is a second order differential equation and then we want to solve this with a boundary condition that  $y$  at  $x$  equal to  $x_0$  is  $y_0$  and  $y$  prime at  $x$  equal to, that is first derivative  $dy$  by  $dx$  at  $x$  equal to  $x_0$  is  $c$ . Now we have some boundary conditions, we want to solve it from 0 to,  $x$  equal to 0 to  $x$  equal to 2 for example some  $x$  equal to some  $x$  value so another value at which is given as 2 in this particular example. So how do we go about solving this, so we said that we can split this into 2 first order equations these 2 first order equations are now given by this  $dy$  by  $dx$  is equal to  $z$  and  $dz$  by  $dx$  is now to become  $az$  plus  $cy$  plus  $dx$ , let me write that is a minus sign probably there.

So we will write this form, so this equation our equation was  $d^2 y$  by  $dx^2$  plus we had a  $dy$  by  $dx$  plus  $cy$  plus  $d$  into  $x$  is equal to 0. So we will write this as, now we are going to write this  $dy$  by  $dx$  that is  $y$  prime we are going to write that as  $z$  and we are going to say we are going to say  $dz$  by  $dx$  is equal to minus  $a$ . So that is it,  $z$  right minus of  $az$  plus  $cy$  plus  $d$  into  $x$  now, we have boundary conditions given as  $y$  at  $x$  equal to 0 is equal to  $y_0$  and  $y$  prime that is  $z$  at  $x$  equal to 0 as, okay.

Now that is our boundary conditions, now with this, now how do we solve this we would write say  $y$  at  $x$  plus  $h$  right you will write that as, we have done  $y$  at  $x$  plus we want to solve this  $z$  is the right hand side. So I would write this as  $1$  over  $6$  times  $k$ , let do the second order to begin with we will then solve this for 4th order also. So I will write it as  $k_{z1}$  plus  $k_{z2}$  by 2. So let us do the second order first so now that is what you would do.

So that is  $k_{z1}$  and  $k_{z2}$  that is what you would write and then similarly, I would write  $z$  at  $x$  plus  $h$  will now be equal to  $z$  at  $x$  plus half times  $a$  into now again. So we would write here I would write it as  $k_{y1}$  plus **a mistake** here  $k_{y1}$  and  $k_{y2}$  and  $k_{z1}$  you would write use notation  $k_y$  for the  $y$  thing and  $k_z$  for the  $z$ ,  $k_{z1}$  plus  $k_{z2}$  by 2.

(Refer Slide time: 13:01)

The chalkboard contains the following handwritten equations:

$$\frac{d^2 y}{dx^2} + a \frac{dy}{dx} + cy + dx = 0$$

$$\frac{dy}{dx} = z \quad y(x=0) = y_0$$

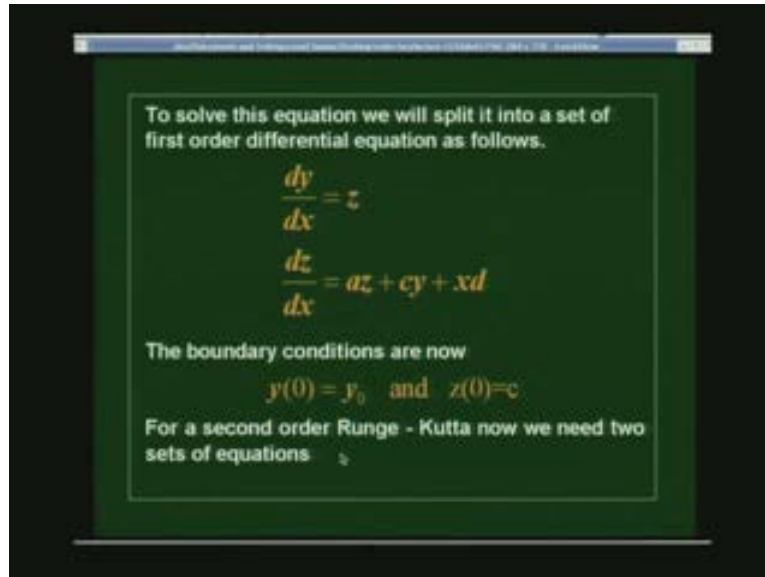

$$\frac{dz}{dx} = -(az + cy + dx) \quad z(x=0) = c$$

$$y(x+h) = y(x) + \frac{1}{2} (k_{y1} + k_{y2})$$

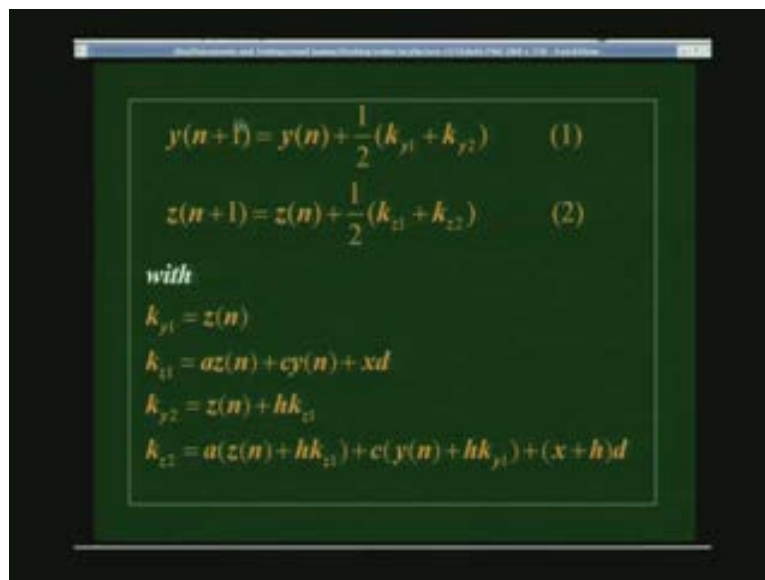

$$z(x+h) = z(x) + \frac{1}{2} (k_{z1} + k_{z2})$$

Okay that is what you would write so now this is the 2 equations which we have to solve so now the point is to find out what is this  $k_{y1}$   $k_{y2}$   $k_{z1}$   $k_{z2}$  is, that is what we are going to now write down so let us summarize this once again.

(Refer Slide time: 13:14)

(Refer Slide time: 13:15)

So I want to solve this equation, these 2 first order equations. Okay that is actually a minus sign there using a second order Runge Kutta scheme and I would just write it as y at the next point as y at the first point plus this  $k_{y1}$  plus  $k_{y2}$  and  $k_{z1}$  plus  $k_{z2}$  for this  $z_1$  y and z would go by these 2 quantities. So y will proceed using  $k_{y1}$  and z will proceed using  $k_{y1}$  and  $k_{y2}$  and z would proceed using  $k_{z1}$  and  $k_{z2}$  starting from the initial value we

would compute the next values using this second order Runge Kutta or 1 level predictor corrector scheme. So now the question is what is this  $k_{y1}$  would be and how do we write that  $k_{y1}$  as so that is your, so remember  $z$  next step is  $z$  plus  $k_z$  and the  $y$  next step is  $y$  plus  $k_y$ .

So now let us compare this with the first order equation which we wrote. So when you write  $dy$  by  $dx$  as  $f$  of  $x, y$ . Our  $k_1$  was  $f$  of  $x, y$  and  $k_2$  was  $f$  at  $x$  plus  $h$  and  $y$  plus  $k_1$  that is what we had written as  $k_2$ , so now we do exactly the same but now there are 2 such equations. So we have to write now  $k_{y1}$  and  $k_{y2}$  and  $k_{z1}$  and  $k_{z2}$  etcetera that is all we had to do here. Okay  $k_{y1}$  as  $f$  at  $x, y$  if it is in  $y$  this is in  $y$  and we say  $k_{y2}$  is now  $f$  at in general it can be a function of  $xy$  and  $z$ . So we will say  $x$  plus  $h$  right  $y$  plus  $k_{y1}$  and you can have  $z$  plus  $k_{z1}$ .

Okay that is the only difference so you see this second equation here can be a function of  $xy$  and  $z$ , so the  $xy$  and  $z$  okay so to evaluate  $k_y$ . We were to first get  $k_{z1}$ , so we cannot evaluate this in 1 shot. So we have to do that in the series that is the only thing which we have to be careful about so when we compute this 1 here, so let me compute this for this so we want to do this first we have to get  $k_{z1}$ . So we will write it in this form.

So we get  $k_{z1}$ , so our idea is to use this we want to evaluate  $z$  at  $x$  plus  $h$  and  $y$  at  $x$  plus  $h$  so to do that we need  $k_{z1}$   $k_{z2}$   $k_{y1}$   $k_{y2}$ . So the way we are going to go about this is first to get  $k_{z1}$ , so that is in this case it is just  $z$  that is just that the function, this is the first equation  $dy$  by  $dx$  and that is equation 1 and this is equation 2. So let me write that carefully, so I will say  $k_{y1}$  that is the right hand side of  $dy$  by  $dx$  is equal to that that is  $z$  at  $x$  and so that is first point  $x$  is equal to 0 and then I would do  $k_{z1}$ . So then I would do  $k_{z1}$  which is this quantity which will be  $az$  plus  $cy$  plus  $dx$  that will be the second quantity

So the way I go to do is that. So first I compute  $k_{y1}$  and then  $k_{z1}$  and then I will do  $k_{y2}$  this I can compute because I am going to say it is so we are going to use a  $h$  here for everything. So minus  $h$  times that so minus plus  $h$  times  $z$  plus  $k_{z1}$  that is what I am going to use to compute  $k_{y2}$ . So we can do  $k_{y1}$  and then we have to do  $k_{z1}$  but before we do  $k_{y2}$  we have to do  $k_{z1}$  because we need  $k_{z1}$  there and then I can do  $k_{z2}$  that is equal to minus  $h$  times  $a$  plus  $k_{z1}$  plus into and the  $c$  times  $y$  plus, minus  $h$  into  $a$  times  $z$  plus  $k_{z1}$  plus  $c$  into  $y$  plus  $k_{y1}$  plus  $d$  into  $x$  plus  $h$  that is our  $k_{z2}$ .

So now we have  $k_{y1}$   $k_{z1}$   $k_{y2}$  and  $k_{z2}$ , so remember that before we compute  $k_{y2}$  we have to compute  $k_{z1}$  and before we compute  $k_{z2}$  we need  $k_{y1}$ . So we have to always do the 1 level thing and then go to the next level in this when you spread the equations into many first order equations, so you could do this for any number um any order that is if you could do a 4th order equation and then you will have 4 such first order equations and then you will have let us say  $k_1, k_2, k_3, k_4$  for each of in this second order case you will have  $k_1, k_2, k_3, k_1$  and  $k_2$  for each of these equations. So care should be taken in just in do the and when you program it the correct order it has to be computed in the correct order. That is the most important thing and that is what I can make mistake in this particular case.

(Refer Slide time: 19:02)

$$\frac{dy}{dx} = f(x,y)$$

$$k_1 = f(x,y) \quad k_2 = f(x+h, y+k_1)$$

$$k'_{y_1} = f(x,y) \quad k'_{y_2} = f(x+h, y+k_1, z+k_2)$$

---

$$k'_{y_1} = h z(x) \rightarrow k'_{y_2} = h(a z + c y + d x)$$

$$k'_{y_2} = h(z+k_2) \quad k'_{y_3} = h(a(z+k_2) + c(y+k_1) + d(x+h))$$

So let me repeat this here. Okay so you had to solve these equations, that is as  $y_n$  plus  $1$  is  $y_n$  plus  $k_{y1}$  by  $2$  plus  $k_{y2}$  second order and similarly for  $z$ . So when you compute as you can see first you compute  $k_{y1}$  and  $k_{z1}$  and then you compute  $k_{y2}$  and  $k_{z2}$  and then you will proceed in this fashion. So this  $h$  can be written either along with the  $k$  or with the on the right hand side of this function. Okay since, we had not included  $h$  here, so we have to have  $h$  on these equations.

So that is the general procedure and you can see that we can do the same thing for the 4th order case also, we will see that in a program this is the program, this program looks a little complicated but in fact this is extremely similar to what we have done in the earlier case that is for the 4th order Runge Kutta but now we have 2 equations.

So let us straight away go to the function, so the function which we are trying to solve is the following I split that function into 2 first order equations. So let me write the second order equation and then split that into 2 first order equations, so the quantity which we want to solve is the following it is  $y$  double prime is equal to we are going to write  $5$  minus  $4y$ ,  $5$  minus  $4y$  plus  $5$  times  $y$  prime. So that is the equation which we are going to solve so  $5$  minus  $4y$  minus  $5y$  prime that is the equation.

We are going to write this as 2 things we are going to write  $y$  prime is equal to  $z$  and  $z$  prime equal to  $5$  minus  $4y$  plus  $5z$ . So in the program in general we could have an  $n$ th order differential equation and  $n$  such first order equations. So since our aim here is to solve these things numerically we should also see how we develop an algorithm for this. So one thing which we should we will do is that when you have an  $n$ th order equation like this each the solutions will now be both  $n$ th order equation like this and we will have solution of  $y$  and  $y$  prime and  $y$  double prime all the way to  $y_n$  right that is  $n$  minus  $1$ .

So that will be our solution set we will have all of them as a function of x, so we call them as  $y_0$  we put them in an array and this is called  $y_0$  and  $y_1, y_2$  etcetera to  $y_n$  minus 1 that is what we will do in the program.

(Refer Slide time: 22:14)

$$y'' = 5 - 4y - 5y'$$

$$y' = z$$

$$z' = 5 - 4y + 5z$$

$$y, y', y'', \dots, y^{(n-1)}$$

$$y[0], y[1], y[2], \dots, y[n-1]$$

So remember when you have a higher order equation, so I write each of those solutions as the elements of an array. So now this is the  $y$ ,  $y_0$  is  $y$ ,  $y_1$  is the first derivative  $y_2$  is the second derivative etcetera. So our equation in that language will transfer this  $z$  is now  $y_1$  so now my equation is actually  $y$  prime equal to  $y$  of 1 and  $y_1$  prime is equal to 5 minus 4  $y_0$  plus 5  $y_1$  minus actually minus  $5y_1$ .

So that is the way you would write. So  $y_0$  is  $y$  and  $y_1$  is the first derivative of  $y$  that is what you will write here so that is the way I have written here so this is the first equation this is the first derivative so you have 2 derivatives now that is the first derivative is just  $y_1$  and the second derivative that is the derivative of  $y_1$  is given by derivative of derivative of  $y_1$  that is the second derivative is given by 5 minus 4  $y_0$  minus  $5y_1$ .

So that is what the equation is we are going to solve. So now we have the other boundary conditions, the boundary conditions are specified in the main program that is my main program here. In the main program, we have the upper limit and the lower limit, so I am going to solve this, the limit  $x$  equal to 0 to  $x$  equal to 2. So now what we are going to solve this one, so we are going to solve this 1 from  $x$  equal to 0 to  $x$  equal to 2. So that is what we are going to do and then now we have as I said  $y$  is now I got 2.

So  $x$  and  $y$  are pointers and this is now, I have 2 elements in this array so I am getting a 2 here, so there are 2 elements here in this array  $y_0$  and  $y_1$  because my order is 2. So put that  $m$  as 2 that is my order, so this specifies my order and  $n$  would be the number of points I would use to solve but I am going to do this in this particular program using adaptive step size, so this has everything now.

So I can change the order here and then this program would work for any order of the differential equation provided you give all the boundary conditions at the initial position and it will run for a using adaptive step size. Okay let us look at that, so now we have the boundary conditions specified here both the boundary condition is  $y_0$   $y_1$  both are 0, that is so we have  $xy$  at this point  $y$  is 0 and this point  $z$  is 0 at  $x$  equal to 0,  $y$  is 0,  $z$  is 0 that is what we have, that is that translates in this language to at  $x$  equal to 0,  $y$  of 0 equal to 0,  $z$  of 0 equal to 0. Okay so that is our boundary condition.

So now given that boundary condition I can start from  $x$  equal to the lower limit and go all the way to the upper limit. So I start with  $x$  equal to the lower limit, so  $x$  is a pointer here which gives you that so now I call Runge Kutta scheme of order 4 and I pass the order of the equation right this is we saw in the last class, that this is the step size which we suggest. So  $h$  is the step size which we suggest which actually it asks for here.

So the program asks you to enter the station for the step size and then it reads the step size from the screen and it will modify the step size by using an adaptive step size algorithm. So here is the step size and here is the pointer to the function which contains all my derivatives, so now this order will be passed on to will be important in dimensioning the derivatives, how many derivatives are these.

So if it is  $2m$  is 2 there are 2 derivatives and  $x$  and  $y$  are the values  $x$  is the value at which we want to now do the calculation. So we go from  $x$  to  $x$  plus  $h$  and  $y$  is the solution set which will be returned and  $h_n$  would be the distance to the next step, the adaptive step size would tell you what the next step should be used as that is what we will put that back and go back, we will put that as  $h$  here and goes back here and goes to the next  $x$  value.

So this program would return to us the next  $x$  step and so if you give  $x_0$   $y_0$  to start with here we give a  $x_0$   $y_0$  and it returns the solutions at  $x$  plus  $h$  and the  $y$  values at  $x$  plus  $h$  that is  $y$  and  $y_1$   $y_0$  and  $y_1$  that is the first, the function and its first derivative because the order is 2. So that is what this program would do.

Okay that is the main function now this just calls this program. Now in this program, now we have to have the  $y$ 's which is again the same dimension as the  $y$ 's and then now we have the derivative here now the derivative  $d y d x$  it is also now a which I call the  $dy dx$  which is a derivative this also now is an array of dimension 2 that is 1 thing which you have to remember. So now this  $dy dx$  is a derivative is a array of dimension 2 that is the derivative of the this equation and the derivative of that.

So now this derivative is called  $dy dx_0$  and this derivative is called  $dy dx_1$ . so these are the 2 equations which we are going to solve so this is this left hand side is called  $dy dx_0$  and this is called  $dy dx_1$  that is what we are going to use.

So basically  $d y dx_0$  will appear in all  $k$ 's  $k_y$  once that is the first derivative so all the  $k_{y_1}$  is that will enter and the  $k_{z_1}$  it will enter as  $dy dx_2$ ,  $dy dx_1$ . So now let us see that so now again so we are going to use an adaptive step size as I said, so here we will now start with

these values, so whatever  $x$  value is given to this program. So let me write this scheme here. So remember, so we want to start from  $x$  equal to 0 so we start from  $x$  equal to 0 and we are going to give a so in the main program.

So the main program what it does is, it takes some main program just takes  $x$  and  $y$  value it takes  $x$  value and  $y$  at  $x$  value and  $y$  prime at that  $x$  value that is what this program is going to do and it is going to call from this main program and it is going to call this Runge Kutta 4 that is why I call  $rk_4$ , the Runge Kutta 4 and then so this program would calculate  $y$  at  $x$  plus  $h$  and  $y$  prime at  $x$  plus  $h$ .

So it would calculate that given this so now to determine this  $h$ , so we also pass an  $h$  to this program as a guess value but this program would actually call, it will actually look for, it will return to this 1 these values  $y$  at  $x$  plus  $h$ ,  $y$  prime at  $x$  plus  $h$  and a  $h$  next, so  $h$  next which I call  $h_n$  all these things are returned to this and actually  $x$  plus  $h$ .

So that will be returned to this and now what we do here is to now replace these quantities which is going to be passed on to this as these quantities that is  $y$  at  $x$  plus  $h$  and  $y$  prime at  $x$  plus  $h$  and  $x$  by  $x$  plus  $h$  next and then it goes back here as the initial value and then it will compute the next step and comes back here again. Okay that is what we wanted to do, I hope that is clear. So that is what is done here, so now we have we have got this  $y_0$   $y_1$ , so remember each time this program is called that is each time this  $rk_4$  Runge Kutta 4 is called it gets a new  $x_0$  and  $y_0$  value. So that is from the main program each time this calls this function it gets a new value of  $x$  and  $y$ .

So that is what it is going to use for the next time step so this gets  $x_0$   $y_0$  as the value and it just simply writes it on to a file and it goes back and calls it again. So every time it is called it is going to call with the new  $x_0$   $y$ , that is  $x$  plus  $h$  and  $y$  at  $x$  plus  $h$  and then  $x$  plus  $2h$  and  $y_0$  and  $y_1$  at  $x$  plus  $2h$  etcetera. So for this program it is always getting  $y_0$  and  $y_1$ , so for this guy which does the  $rk_4$  it is always getting these values  $x$  and  $y$  prime at  $x$  what is that  $x$  keeps changing as we make each calls. So that is the part here and then we store that thing, so and then we will as we have  $d_1$  in the first order case the first order differential equation now the only change here is that we have instead of  $y$  alone now we have  $y_0$  and  $y_1$ .

So now we have the initial values given as  $x_0$  and  $x$  that is  $x_0$  is the  $x$  value at which we are going to evaluate this and then  $y_0$  at that point which I call  $y_0$  because  $y_0$  is stored as  $y_0$  and  $y_1$  is stored as  $y_1$  and then I will go here and then I compute called this a function called derives remember this is exactly the same as the first order differential equation case only thing is now this derives which is the function which we looked at now returns 2 derivatives  $dy/dx_0$  and  $dy/dx_1$  and we have passed 2  $y$  values  $y_0$  and  $y_1$  that is the point. So now and then using that  $y_0$  and  $y_1$  and  $dy/dx_0$  and  $dy/dx_1$  we compute the new values of  $y_0$  and  $y_1$ .

Okay so now this idea is to do now we are doing a 4th order Runge Kutta and we want to compute  $y$  of 0 as  $y$  of 0 plus 1 by 6 times  $k_{y1}$  plus  $k_{y2}$  plus  $k_{y3}$  plus  $2k_{y1}$  plus  $2k_{y2}$  plus  $2k_{y3}$  plus  $k_{y4}$ . Okay that is what we are going to compute, so we do each step, so one we

compute  $k_{y1}$  and I will update my  $y_0$  as  $y_0$  plus  $k_{y1}$  by 6 and similarly  $y$  of 1, I will write  $y$  of 1 as 1 by 6 times  $k_{z1}$  plus 2  $k_{z2}$  plus 2  $k_{z3}$  plus  $k_{z4}$  okay.

So now this is the  $dy/dx$  2 these are  $dy/dx$  1, 0s and these are  $dy/dx$  0 and these are  $dy/dx$  1. So again when I compute this I will compute  $k_{y1}$  and  $k_{z1}$  that is  $dy/dx$  0 and  $dy/dx$  1. I will update this, I will do this step first and then I will do this step then I go around and compute  $k_{y2}$  and  $k_{z2}$  so every time I compute this thing I update my  $y$  by adding that part into the  $y_0$ , so that is what this program is doing.

(Refer Slide time: 34:36)

So, first step is to compute  $k_{y1}$  and  $k_{z1}$  that is returned as  $dy/dx$  0 and  $dy/dx$  1 in this thing because it is in an array here. So the advantage of writing this in the array form is that you can extend this program to any order by just changing the order  $m$  by setting  $m$  equal to 2, 3, 4 etcetera.

So then this array dimension would automatically change because we have dimension data is  $m$  plus 2 here. So we get array dimension automatically changed that is the first step and then we go from  $x$  going from  $x$  plus  $h$  by 2 that is the next step and then we will compute now  $k_{y2}$  and  $k_{z2}$  that is again the derivatives at that values. So that is what we are going to compute there.

So now we are updating the  $y$  values, so now we want to compute  $k_{z2}$  and  $k_{y2}$ , remember if I want to compute  $k_{z1}$  in this program this is the equation which you are going to solve right. So,  $k_{y1}$  is  $z$  plus  $k_{y2}$  is  $z$  plus  $k_{z2}$  right. So we will write that again here. So then I want to compute this, so what I need, so I computed first  $k_{y1}$  and  $k_{z1}$  and I have added that into this part, that is finished.

So now I want to compute the next step that is  $k_{z1}$   $k_{y2}$  and  $k_{z2}$ . So remember  $k_z$ ,  $k_{y2}$  is  $y_2$  is actually in this case  $z$  plus  $k_{z1}$  that is what  $k_{y2}$  is, okay this is  $k_{y2}$  what is coming as  $y$

here is the  $k_{y2}$ . So that is  $k_{y2}$  is that  $dy$  by  $dx$  equal to  $z$ . So this equation has the  $k_y$  and this solution of this gives us the  $y$  is a solution of this gives us the  $y_1$  that is the  $z$ . So this has the  $k_{z1}$   $k_{z2}$  etcetera and this will be  $k_{y1}$   $k_{y2}$  right hand side of this is  $z$ . So  $k_{y2}$  is  $z$ ,  $k_{y1}$  was  $z$  and  $k_{y2}$  is  $z$  plus  $k_{z1}$  and  $k_{z1}$  was  $5$  minus  $4y$  minus  $5z$ . Okay  $5z$  and now  $k_{z2}$  would be then  $5$  minus  $4y$  plus  $k_{y1}$  right. So that is here a minus  $5$  into  $z$  plus  $k_{z1}$ . So in this program what I do is I pass this new  $y$  value and then new  $z$  value into the function and it will return the right hand side for both  $k_{y2}$  and  $k_{z2}$ . So that is what it would return.

(Refer Slide time: 37:38)

$y' = 5 - 4y - 5z$   
 $y = z$   
 $z' = 5 - 4y - 5z$   
 $k_{y1} = z, k_{y2} = z + k_{z1}$   
 $k_{z1} = 5 - 4y - 5z, k_{z2} = 5 - 4(y + k_{y1}) - 5(z + k_{z1})$

So I just computed that  $y$  value  $y_0$  and this is  $y$  and this is  $z_{y1}$  is  $z$  and  $y_0$  is  $y$  remember that. So now when it is updated as derivative by 2 and this divided by 2 in the case  $z_2$  there is half here. So that is what we are doing. So we compute this at the  $k_{z2}$  and by passing this function this as a new  $y$  value into the function which returns the derivative. So I have a function which simply returns the right hand side of these 2 equations to that equation now I pass  $z$  as that and  $y$  as this and it will return the right hand of these 2 as  $dy/dx$  0 and  $dy/dx$  1.

So that is what is just done here. So I updated my  $y_0$  and  $y_1$ , okay and  $yy_0$  and  $yy_1$  and then I pass that into this function and then we will return the  $dy/dx$  0 and  $dy/dx$  1 and then that will give me the derivative and I use now this equation this equation and I add this term now to the  $y$  value, that is  $k_{y2}$  by 3 and  $k_{z2}$  by 3 that is what I am doing here, that is what is done here.

So I will update that thing here and then I do that similarly for  $k_{y3}$  now this step is straight forward, so now this is same as this now I do for  $k_{y3}$  again I update my  $yy_0$  and  $yy_1$  call the derives to get the derivative and update my  $y_0$  and  $y_1$  and similarly, for  $k_4$  and then it is the first loop when I do this, I store them that solutions I got as  $y_{n0}$  and  $y_{n1}$ . So that is my predictor in some sense it is my predictor and then this predicted value with

step  $h$  and then I reduce by step to  $h$  equal to  $h_2$  here I reduce by step to  $h$  equal to  $h$  by 2 and I do the same thing now for 2 loops.

That is  $h$  by 2 step and  $x$  plus  $h$  by 2 and  $x$  plus  $h$  and I get the new  $y$  values as we saw in the last class for the case of a first order equation same thing we repeat for the second order equation for with  $y_0$  and  $y_1$  and in the earlier case it was only  $y_0$  that is the only difference and then you compare the error which we get in both cases now there are 2 functions so  $y_{n0}$  minus  $y_0$  by  $y_0$ . So remember,  $y_{n0}$  is what is the  $y$  value obtained at  $x$  plus  $h$  using 1 step that is go from  $x$  to  $x$  plus  $h$  in 1 step and  $y_0$  is a  $y$  value obtained by going from  $x$  to  $x$  plus  $h$  in 2 steps,  $x$  plus  $h$  by 2 and then  $x$  plus  $h$ , now these 2 step values we compare these 2 values that is  $y_{n0}$  minus  $y_0$  divided by  $y_0$  for the absolute value of that.

So then similarly, for  $y_1$ , so and then I add this construct my error function there, I construct my error function here in this way and then I look at my error is less than my tolerance or not if it is less than the tolerance I increase the step by 2 times the  $h$  value which I use, if it is greater than the tolerance I step the, I reduce the step size further to  $h$  by 2 and I restart the whole program whole thing again the whole calculation again.

So that is something which we saw in the last class and then I returned the  $y$  values and the  $x$  values, the  $x$  next values to the main program and the main program will call it with again with the new  $x$  values and new  $y$  values and the process would repeat. So let us and so then in the end we are solving an equation of this form remember that is  $d^2 y$  by  $dx^2$  is equal to  $5 - 4y$  minus  $5 dy$  by  $dx$ . So let us look at this we will just run this program and see there so that is, so now we need to pass the step size the order of the equation is 2, the second order equation and the upper limit is 2 and the lower limit is 0 it is solving from 0 to 2.

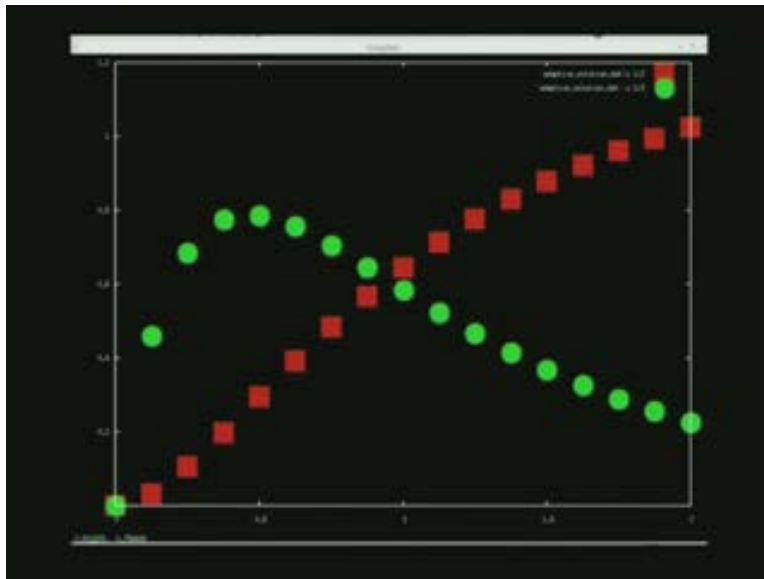

(Refer Slide time: 43:02)

So I would just enter a step size let us say “point 5” and it will solve that now we just brought that function so we get the data file we get is actually adaptive solution dot dat. So we will plot that, so we have now in the solution set we have now this I should just show you that solution how it is written, now the solution is written in this form in the main program I write the solution as x that is the x value and the y value and its derivative. So if I use 1 colon 2, 1 and 2 then it is x versus y and if I use 1 and 3 then x versus y prime that is the derivative of y so the complete solution as I said the second order equation the complete solution means actually obtaining both the function and y as the function of x and it is derivative as a function of x so that is what, so now here is the solution of the equation.

So now this is x versus y I am plotting x versus y and this is the y value as the function of x, you can also plot the x you can also plot the next part that is the derivative. So that will be using 1 colon 3 that is x and it is derivative. So as I said the solution is written as first column is x, second column is y and the third column is the y prime that is the derivative, okay now that is the derivative.

(Refer Slide time: 43:36)

So you can have the solution the y the solution 2 function that is the y value and its derivative as you can see the derivative increases here and it decreases here because this function is saturating to some value here. Okay so now that is the solution of the equation of this form that is  $y'' = 5 - 4y - 5y'$  it is a second order equation with 2 boundary conditions specified at the initial value  $x$  equal to  $x_0$ .

So now we end the discussion on ordinary differential equations here with just 1 more point that is, so far we have only seen how to solve the first order equations the initial value problems we saw how to solve order  $n$ th order equations or  $n$ th order ordinary differential equations as an initial value problem in the case where some of the boundary conditions are specified at 1 point and the other boundary conditions are specified other

m minus n boundary conditions are specified at the other end for example, in this case you could have the 1 boundary condition specified at x equal to 0.

Let us say for example, y is specified at x equal to 0 and z is specified at x equal to 2 or y prime is specified at x equal to 2 in that kind of cases, which is called the boundary value problem. We can still in some of the problems we can still use these techniques and those are called normally the shooting method in which what we do is we again convert this into an iterative scheme. So we start with so let us look at a particular example, so let us say we are given x equal to 0, y equal to 0 and x equal to 2y equal to some  $y_1$  okay, z equal to some  $z_1$  that is the boundary condition given it could be even y.

So but let us say 1 end we are given the derivative and other end we are given the um the y value it could be that both ends of y values are specified 1 boundary condition is specified at x equal to 0 and other boundary condition is specified at x equal to 2. So in that case what we could do is um we could use exactly the same method you convert this into 2 first order equations.

(Refer Slide time: 46:59)

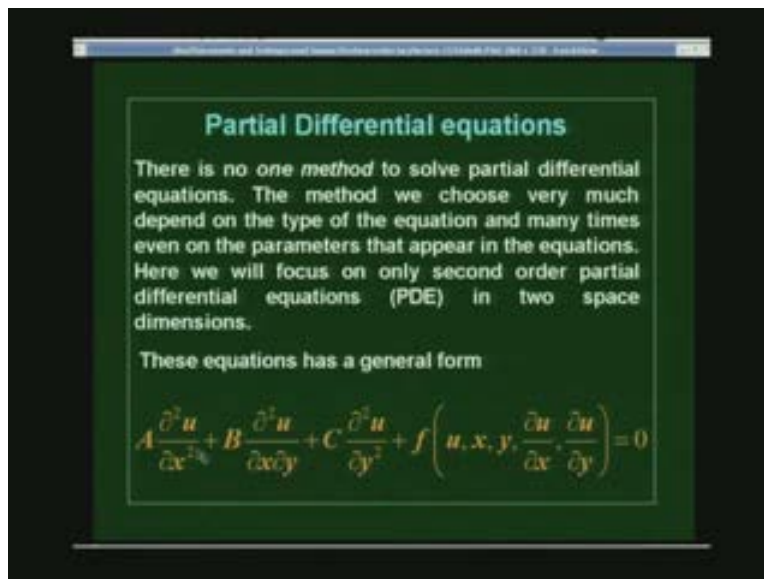

Now to use the Runge Kutta scheme as you see that we always use a scheme like this that is we are starting from  $y_0$  and goes through some value and go to the next value this is at x plus x equal to  $x_0$  and then go to  $x_0$  plus h. So we are always using a scheme like that, that is we are using the y at x plus h as y at x plus 1 by 6 times  $k_{y1}$  plus  $k_{y2}$  plus  $k_{y3}$ ,  $2k_{y1}$  plus  $2k_{y2}$  plus  $k_{y3}$ ,  $y_2$   $y_3$  and  $y_4$ . Okay and 1 by 6 that is the kind of scheme, we are using so to go to x plus h we need xy at x, so similarly for z so if you want to use that if you have boundary conditions specified at the 2 ends then we cannot use this because we do not know if this x value is not specified then you cannot use this.

So that cases what do you do is you make a guess you say that okay I guess I make a guess for what the y values are  $y_0$  and  $y_1$  are at x equal to  $x_0$  only 1 is given other one, I

make a guess and then I go all the way to the other end and then I compare the y value I obtained at the other end satisfy the boundary conditions. So that is called a shooting method so you make a guess at the initial value and then you go to the other end if you cannot do this calculation because you did not know what these initial values were and you knew only 1 initial value and the other value was actually the other boundary condition is specified at the other end and then I make a guess for this and then I go all the way in this particular case it is actually making a guess for this because I have been given z at the x equal to 2 not at x equal to 0.

So I make a guess for this value at x equal to 0 and then I go all the way to x equal to 2 and then I see the value y obtained on that side is the same as this or not and if it is not I make an adjustment into our initial guesses again and then I go there again to that point. So in this iterative scheme I can actually obtain a solution to that equation a little more tedious and but sometimes not too inefficient method called shooting method.

(Refer Slide time: 49:27)

So with this we stop the discussion on the ordinary differential equations and now we would go over to a discussion on partial differential equations that will be our next topic to look at. So far we have only looked at equations which are of 1 variable type a derivative with respect to only one independent variable, we have only everything as a function of x alone. So both z that is y prime and y in this particular case were the function of x alone but we could have them as functions of many variables, many independent variables.

In that case this is differential equations would have derivative with respect to all those independent variables for example, here is a general partial differential equation it is a function variable u which is what we want to find and u and its derivatives as what we want to find, so if you want to solve this equation what we mean by that is we want to find out u as a function of x and y. So x and y are both independent variables, so you

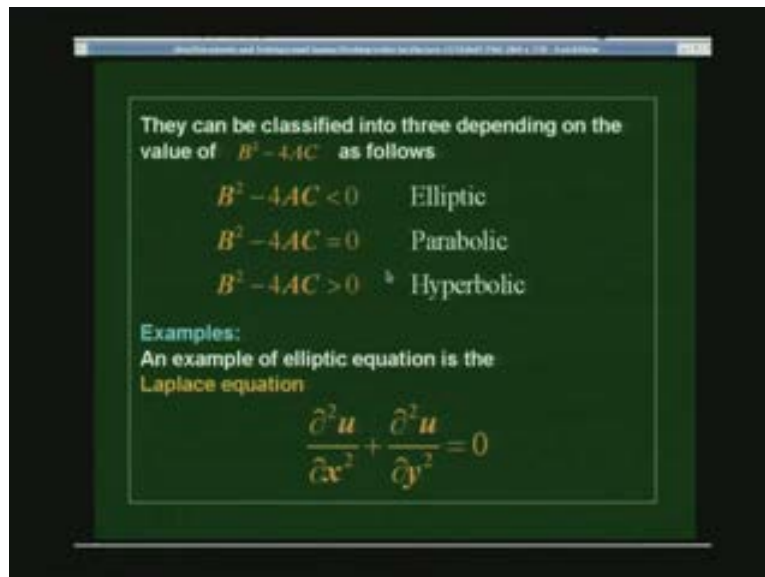

want to find  $u$  as a function of  $x$  and  $y$  and derivative of  $u$  as a function of  $x$  with respect to  $x$  and  $y$  and derivative of  $u$  as a function of  $y$  with respect to  $x$  and  $y$ . So that will be the, that would be what you mean by finding the solution of this partial differential equation.

So how do we go about doing that. That will be the discussion which will be which we will do now just add the general partial differential equation in this form with coefficients  $a$ ,  $b$  and  $c$  they are some constant coefficients  $a$ ,  $b$  and  $c$  and we have a differential equation of this form and then some function of and this here some function of  $u$   $x$   $y$  derivative of  $u$  derivative of  $y$  etcetera.

So we have a general differential equation of this form. So remember that this can be any function of  $u$   $x$   $y$  derivative of  $u$  with respect to  $x$  derivative of  $u$  with respect to  $y$  and then we can classify this differential equation into 3 categories called elliptical parabolic and hyperbolic, not that we need this classification to solve this equation but we will try to do 1 example or look at 1 example from each of these classes and then how to solve that and there is no, one thing we should keep in mind is that there is no general method for each class of this equation.

(Refer Slide time: 51:14)

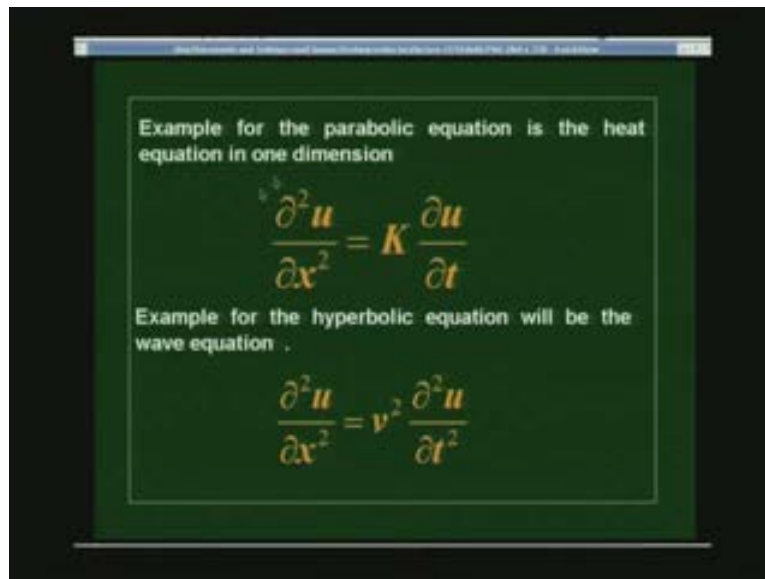

It is not that if we could classify a differential equation into an elliptic form then there is partial differential equation into as an elliptic partial differential equation and there is 1 numerical method and then there is a parabolic equation there is an another numerical method etcetera. They do not exist actually for the difficulty with partial differential equations is that the method which we use to solve partial differential equation is specific to a particular equation, there is there are a very few methods which are general enough so that you can use it for a class of problems.

So the technique which we use to solve partial differential equations depends very much on the sometimes even the coefficient sitting in front of these derivatives the range of those coefficients etcetera. We will look at that in the coming classes here, let us just see this as 3 different classes so that  $b^2 - 4ac$  is less than 0 as elliptic for example, the equation would be laplace's equation which you are familiar with in electrostatics etcetera.

So this laplace's equation is a case of elliptic partial differential equation remember a, b and c, so a, b and c are the coefficients of the 2 second derivatives and a and c are the coefficients of the 2 second derivatives with respect to variable x and y respectively and the b is the coefficient of, cross second derivative  $\frac{\partial^2 u}{\partial x \partial y}$ . So in the case of laplace's equation we have a as 1 and c as 1, b is 0 and f this function is 0 that is what laplace's equation is and then we have that as satisfying this as b is 0.

So we have a c is less than 0 a and c are the same sign, so a c is less than 0 so it is an elliptic equation if you had a minus sign here that would be a case where again b is 0 but a and c have now minus opposite signs. So it will be a positive case so that will be case of hyperbolic equation.

(Refer Slide time: 54:10)

So we will see the wave equation as an example of, so now if you had one of them 0, that is we have only 1 derivative with respect to we only had this derivative and we did not have the second derivative with respect to y but we had some first derivative with respect to y that is in this equation if you have only 1 of them a or c as non 0 and b is also 0 and then some function here which is non 0 function that kind of equations would be parabolic equations. Okay as I said equation for an elliptic equation is an example for an elliptic equation is laplace's equation and an example for a parabolic equation here is a parabolic equation is a heat equation that is where  $b^2 - 4ac$  is 0, that is the heat equation or the diffusion equation.

We will solve, we will look at solutions of this equation also and then an hyperbolic equation would be the wave equation. So that is the 3 different examples which you would be interested in looking at so remember laplace's equation as an example of elliptic equation and heat equation or a diffusion equation as an example of parabolic equation and a wave equation as an example of a hyperbolic equation. So one other thing which we always do in the methods which we use here that is heat is not a general method for solving partial differential equation unlike Runge Kutta scheme, which can be used for a class of ordinary differential equation there is no 1 method to solve a partial differential equation but the method which we would be looking at here is mostly using, replacing the derivatives by its discrete form.

(Refer Slide time: 55:12)

It then follows that

$$\frac{q(x) - q(x + \Delta x)}{\Delta x} \Delta y + \frac{q(y) - q(y + \Delta y)}{\Delta y} \Delta x = 0$$

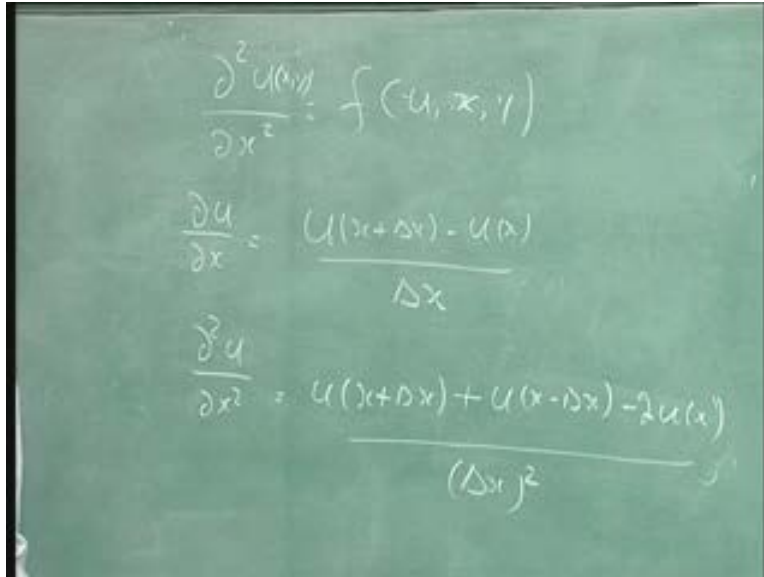

$$[q(x) - q(x + \Delta x)] \Delta y + [q(y) - q(y + \Delta y)] \Delta x = 0$$

$$\frac{\partial q}{\partial x} + \frac{\partial q}{\partial y} = 0$$

So that is we write an equation of this form and then we would replace the derivatives by its difference equation. So that is something which we would be looking at hence, okay so that is we would have let us say we have an equation of del square u by del x square with some function of x some u and x and y you know. Okay so some equation like this so u x and y x is a function of x and y. So and then we would replace we would replace this derivative by its discrete derivative that is we would write del u by del x for example, you could write it as u at x plus delta x minus u at x divided by delta x.

So that will be a simple forward differencing scheme and similarly we could write del square u by del x square as u at x plus delta x plus u at x minus delta x minus 2u of x divided by delta x square and similarly for y, and these we will replace these difference equations into this equation into this differential equation here and we will convert this differential equation to a difference equation and solve for these u values at various x values and y values. Okay that is what it is something that we will be doing as a method for solving partial differential equations.

(Refer Slide time: 56:54)

The image shows a green chalkboard with three mathematical equations written in white chalk. The first equation is  $\frac{\partial^2 u(x,y)}{\partial x^2} = f(u, x, y)$ . The second equation is  $\frac{\partial u}{\partial x} = \frac{u(x+\Delta x) - u(x)}{\Delta x}$ . The third equation is  $\frac{\partial^2 u}{\partial x^2} = \frac{u(x+\Delta x) + u(x-\Delta x) - 2u(x)}{(\Delta x)^2}$ .

We will not be looking at more complicated methods for solving partial differential equations in this course. So we will such techniques to solve both laplace's equation and heat equation in the coming few lectures.
