Module-04
Lecture-01
Diffraction Part-01

In this lecture I will start diffraction of light; here first I will explain what is diffraction? And then I will describe single slit and double slit diffraction pattern. Diffraction is defined as the bending of waves around an obstacle or the spreading of waves when they pass through a narrow opening. To explain the diffraction of light wave let us consider a plane wave incident on a long narrow slit of width B .

(Refer Slide Time: 00:58)

According to geometrical optics we expect the region AV of the screen S , S prime to be illuminated and the remaining position known as geometrical shadow to be absolutely dark. However if the observations are made carefully then we find that if the width of the slit is not very large compared to the wavelength of light. Then the light intensity in the region AB is not uniform and there is also some intensity inside the geometrical shadow further if the width of the slit is made a smaller larger amount of light reach in the geometrical shadow.

This is spreading out of wave when it passed through a narrow opening is known as the phenomenon of diffraction and the intensity distribution on the screen is known as diffraction

pattern. Like interference this phenomenon can be explained satisfactorily by assuming a wave character for light. We will see that there spreading out decreases with decrease in the wavelength since the light wave lengths are very small the effects.

Due to diffraction are not easily observed on the other hand sound waves have wavelengths comparable to ordinary objects and our deflected by them. Due to this we hear sound even though we may not be in a direct line to their sources.

(Refer Slide Time: 02:49)

Due to this we hear sounds even though we may not be in a direct line to their source.

In case of light the Diffraction phenomena are usually divided into two classes:

- 1) Fresnel diffraction
- 2) Fraunhofer diffraction

In the Fresnel class of diffraction the source of light and the screen are in general, at finite distance from the diffracting aperture/slit as shown in this figure. On the other hand in the Fraunhofer class of diffraction, the source and the screen are at infinite distances from the aperture/slit.

In case of light the diffraction phenomena are usually divided into two classes Fresnel diffraction and Fraunhofer diffraction. In the Fresnel class of diffraction the source of light and the screen or in general had finite distance from the deflecting aperture or slit as shown in this figure. On the other hand in the front of her class of diffraction the source and the screen are at infinite distances from the aperture or slit.

(Refer Slide Time: 03:31)

Fresnel diffraction

In the laboratory this is easily achieved by placing the source on the focal plane of a convex lens and placing the screen on the focal plane of another convex lens as shown in this figure.

(Refer Slide Time: 03:46)

Fraunhofer diffraction

The two lenses effectively move the source and the screen to infinity because the first lens makes the light beam parallel and the second lens effectively makes the screen receive a parallel beam of light.

(Refer Slide Time: 04:11)

Now I will describe the single slit diffraction patterns due to an infinitely long slit of width b . Let us assume a plane monochromatic wave is incident normally on the slit. Now we want to calculate the intensity distribution on the focal plane of the lens l . When a plane wave front of monochromatic light of wavelength λ is incident normally on the plane of the slit its size is limited at the instant it occupies the plane of the slit.

Now according to principle of Huygens Fresnel at this instant every point of the wave front in the plane of the slit is to be regarded as the origin of secondary spherical reference which is spread out to the right in all directions. The parts of each wavelet traveling normally to the slit are brought to focus at P naught by the lens while the parts traveling at an angle θ with the normal are brought to focus at P on the screen.

So, we can assume that the slit consists of a large number of equally spaced points sources and that each point on the slit is a source of Huygens secondary wavelets which interfere with the waves emanating from other points.

(Refer Slide Time: 05:50)

Let the point sources P at A1, A2, A3 so on and let the distance between two consecutive points be Delta as shown in this figure. Thus if there are n point sources on the slit then b will be = n - 1 Delta. We will now calculate the resultant field produced by these n sources at the point P which receive parallel rays making an angle theta with the normal to the slit. Since the slit actually consists of a continuous distribution of sources.

We will in the final expression let n goes to infinity and Delta goes to 0 such that Delta into n tends to b. Now at the point P the amplitude of the disturbance reaching from A1, A2, A3 so on will be very nearly the same because the point P is at a distance which is very large in comparison to b. However because of even a slightly different path lens to the point P the field produced by A1 will differ in phase from the field produced by A2.

For an incident plane wave the points A1, A2 etc are in phase and therefore the additional path traversed by the disturbance emanating from the point A2 will be A2, A2 prime where A2 prime is the foot of the perpendicular drawn from A1 on A2 B2.

(Refer Slide Time: 07:53)

that the optical paths A_1B_1P and $A_2'B_1P$ are the same. If the diffracted rays make an angle θ with the normal to the slit then the path difference A_2A_2' would be $\Delta \sin \theta$ and The corresponding phase difference, ϕ , would be given by

$$\phi = 2\frac{\pi}{\lambda} \Delta \sin \theta$$

Thus, if the field at the point P due to the disturbance emanating from the point A_1 is $a \cos(\omega t)$ then the field due to the disturbance emanating from A_2 would be $a \cos(\omega t - \phi)$.

This follows from the fact that the optical paths A_1B_1P and $A_2'B_1P$ are the same. If the diffracted ray makes an angle θ with the normal to the slit then the path difference A_2A_2' would be $\Delta \sin \theta$. And the corresponding phase difference ϕ would be 2π by λ into $\Delta \sin \theta$, thus if the field at the point P due to the disturbance emanating from the point A_1 is $a \cos \omega t$. Then the field due to disturbance emanating from A_2 would be $a \cos \omega t - \phi$.

(Refer Slide Time: 08:52)

Now the difference in the phases of the disturbance reaching from the points A_2 and A_3 will also be ϕ and thus the resultant field at the point P would be given by

$$E = a [\cos \omega t + \cos(\omega t - \phi) + \dots + \cos(\omega t - (n-1)\phi)]$$

$$\text{where } \phi = \frac{2\pi}{\lambda} \Delta \sin \theta$$

So here we have to find the resultant of n simple harmonic waves all having the same amplitude and with their phases increasing in arithmetic progression. This can be obtained by using geometrical method discussed in the first lecture of interference of light.

Now the difference in the phases of the disturbance reaching from the point A_2 and A_3 will also be ϕ and thus the resultant field at the point P would be given by $a \cos \omega t + a \cos \omega t - \phi + a \cos \omega t - 2\phi + a \cos \omega t - 3\phi + \dots + a \cos \omega t - (n-1)\phi$ where $\phi = \frac{2\pi}{\lambda} \Delta \sin \theta$

sine theta. So, here we have to find the resultant of n simple harmonic waves all having the same amplitude and with their faces increasing in arithmetic progression.

This can be obtained by using geometrical method discussed in the first lecture of interference of light.

(Refer Slide Time: 09:51)

We can show that

$$\cos \omega t + \cos(\omega t - \varphi) + \dots + \cos[\omega t - (n-1)\varphi]$$

$$= \frac{\sin(\frac{n\varphi}{2})}{\sin(\frac{\varphi}{2})} \cos\left[\omega t - \frac{1}{2}(n-1)\varphi\right]$$

Thus the resultant field becomes

$$E = E_0 \cos\left[\omega t - \frac{1}{2}(n-1)\varphi\right]$$

We can show that $\cos \Omega t + \cos \Omega t - \Phi$ up to $+\cos \Omega t - n - \Phi = \frac{\sin n \Phi}{2 \sin \frac{\Phi}{2}}$ thus the resultant field at Point P becomes $= E_0 \cos \Omega t - \frac{1}{2} n - 1 \Phi$.

(Refer Slide Time: 10:20)

where E_0 is the amplitude of the resultant field, given by

$$R = E_0 = a \frac{\sin(\frac{n\varphi}{2})}{\sin(\frac{\varphi}{2})}$$

and a is the amplitude of each wave.

$$\text{Here, } \frac{n\varphi}{2} = \frac{\pi}{\lambda} n \Delta \sin \theta \rightarrow \frac{\pi}{\lambda} b \sin \theta$$

$$\text{and therefore } \frac{\varphi}{2} = \frac{\pi}{\lambda} \frac{b \sin \theta}{n}$$

In the limit of $n \rightarrow \infty$, $\frac{\varphi}{2}$ will be very small. So $\frac{\sin(\frac{\varphi}{2})}{\frac{\varphi}{2}} \approx 1$ and we have

Where $E_{\theta} = a \frac{\sin n\phi}{\sin \phi} = a \frac{\sin \frac{n\pi b \sin \theta}{\lambda}}{\sin \frac{\pi b \sin \theta}{\lambda}}$ and a is the amplitude of each wave here we can show that $n\phi$ will be $= \frac{\pi b \sin \theta}{\lambda}$ which we can write $= \frac{\pi b \sin \theta}{\lambda}$ and therefore ϕ will be $= \frac{\pi b \sin \theta}{\lambda n}$. In the limit of n tending to infinity ϕ will be very small. So, we can write $\sin \phi$ approximately $= \phi$.

(Refer Slide Time: 11:15)

$$R = E_{\theta} = \frac{a \sin(\frac{n\phi}{2})}{\sin(\frac{\phi}{2})} = na \frac{\sin(\frac{\pi b \sin \theta}{\lambda})}{(\frac{\pi b \sin \theta}{\lambda n})}$$

$$= A \frac{\sin \beta}{\beta}$$

Where $A = na, \beta = \frac{\pi b \sin \theta}{\lambda}$

$$E = A \frac{\sin \beta}{\beta} \cos(\omega t - \beta)$$

The resultant vibration will therefore be a simple harmonic and the amplitude of this varies with angle θ . Since, the position of point P depends on θ , the amplitude of the resultant vibration will vary with the position of point P on the screen.

And we have resultant amplitude $E_{\theta} = n$ times $a \frac{\sin \phi b \sin \theta}{\lambda}$ divided by $\frac{\pi b \sin \theta}{\lambda}$ this we can write $= A \frac{\sin \beta}{\beta}$ where $A = n$ times a and $\beta = \frac{\pi b \sin \theta}{\lambda}$. So, the resultant field at the point P becomes $= a \frac{\sin \beta}{\beta} \cos \omega t - \beta$. Thus the resultant vibration is a simple harmonic and the amplitude of this varies with angle θ .

Since the position of point P depends on θ the amplitude of the resultant vibration will vary with the position of point P on the screen.

(Refer Slide Time: 12:22)

The intensity of the resultant vibration is given by

$$I = I_0 \frac{\sin^2 \beta}{\beta^2}$$

where $I_0 = A^2 = n^2 a^2$ represents the intensity for $\theta=0$, i.e. intensity of the resultant vibration of the waves travelling in a direction perpendicular to the plane of the slit. In this case all waves will arrive in phase at point P, resulting maximum intensity of the resultant wave.

The intensity of the resultant vibration is given by $I = I_0 \sin^2 \beta / \beta^2$ where $I_0 = A^2$ which represents the intensity for $\theta = 0$ that is intensity of the resultant vibration of the waves traveling in a direction perpendicular to the plane of the slit. In this case all waves will arrive in phase at Point P resulting maximum intensity of the resultant wave. Now I will discuss positions of maxima and minima on the screen.

(Refer Slide Time: 13:14)

Positions of Maxima and Minima:

We have
$$I = I_0 \frac{\sin^2 \beta}{\beta^2}$$

Minimum Intensity Positions:

The intensity will be Zero in the diffraction pattern at the position where $\sin \beta = 0$

$$\Rightarrow \beta = m\pi, m = \pm 1, \pm 2, \pm 3, \dots, \text{but } m \neq 0$$

Principal Maxima:

When $\beta = 0, \left(\frac{\sin \beta}{\beta}\right) = 1$ and $I = I_0$ which

corresponds to the principal maximum intensity.

Condition for minima is
$$\beta = \frac{\pi b \sin \theta}{\lambda} = m\pi$$

We have a intensity of the resultant wave $I = I_0 \sin^2 \beta / \beta^2$. So, the intensity will be 0 in the diffraction pattern at the position where $\sin \beta = 0$ that is $\beta = m\pi$ where $m = +1, -1, +2, -2, +3, -3$ so on. But m should not be $= 0$ and when $\beta = 0$ we have $\sin \beta = 0$

by $\beta = 1$ and $I = I_0$ which correspond to principle maximum intensity. And the condition for so condition for minimize $\beta = \pi b \sin \theta$ where $\lambda = m \pi$ and the condition for principle Maxima is $\beta = 0$.

(Refer Slide Time: 14:17)

or $b \sin \theta = m\lambda; m = \pm 1, \pm 2, \pm 3$

The first minimum occurs at $\theta = \pm \sin^{-1}(\frac{\lambda}{b})$,

The second minimum at $\theta = \pm \sin^{-1}(\frac{2\lambda}{b})$, etc.

Since $\sin \theta$ cannot exceed unity, the maximum value of m is the integer which is less than or equal to $\frac{b}{\lambda}$.

The positions of minima can be explained by simple qualitative arguments. Let us consider the case $m=1$. The angle θ satisfies the equation

$$b \sin \theta = \lambda$$

So, for minima we have $b \sin \theta = m \lambda$ where $m = +1, -1, +2, -2, +3, -3$ so on. So, the first minimum occurs at $\theta = \pm \sin^{-1}(\frac{\lambda}{b})$ and the second minimum will occur at $\theta = \pm \sin^{-1}(\frac{2\lambda}{b})$ etc. Since $\sin \theta$ cannot exceed unity the maximum value of m is the integer which is less than or $= \frac{b}{\lambda}$. The position of minima can be explained by simple qualitative argument. Let us consider the case $m = 1$ the angle θ satisfy the equation $b \sin \theta = \lambda$.

(Refer Slide Time: 15:20)

We now we divide the slit into two halves as shown in this figure consider two points A and A prime separated by a distance $b/2$. Clearly the path difference between the disturbance emanating from A and A prime is $b/2 \sin \theta$ which in this case is $\lambda/2$. The corresponding phase difference will be π and the resultant disturbance will be 0. Similarly the disturbance from the point B will be cancelled by the disturbance reaching from the point B prime.

Thus the resultant disturbance due to the upper half of the slit will be canceled by the disturbance reaching from the lower half and the resultant intensity at Point P will be 0. In a similar manner when $b \sin \theta = 2\lambda$, we divide the slit into four parts. The first and the second quarter cancelling each other and the third and fourth quarter cancelling each other, similarly when m is $= 3$ slit is divided into 6 equal parts and so on. Now let us find out the position of secondary maxima.

(Refer Slide Time: 16:42)

Positions of secondary maxima

$$I = I_0 \frac{\sin^2 \beta}{\beta^2}$$

In order to determine the position of Maxima, we differentiate this equation w. r. t. β and set it equal to zero. Thus

$$\begin{aligned} \frac{dI}{d\beta} &= I_0 \left[\frac{2 \sin \beta \cos \beta}{\beta^2} - \frac{2 \sin^2 \beta}{\beta^3} \right] = 0 \\ &= 2I_0 \frac{\sin \beta}{\beta^2} \left[\cos \beta - \frac{\sin \beta}{\beta} \right] = 0 \\ &= \frac{2I_0 \sin \beta}{\beta^2} \left[\frac{\beta \cos \beta - \sin \beta}{\beta} \right] = 0 \\ &= 2I_0 \frac{\sin \beta}{\beta} \left[\frac{\beta \cos \beta - \sin \beta}{\beta^2} \right] = 0 \end{aligned}$$

So, we have our intensity $I = I_0 \sin^2 \beta / \beta^2$. So, in order to determine the position of maxima we differentiate this equation with respect to β and set it $= 0$. thus $dI / d\beta = I_0 [2 \sin \beta \cos \beta / \beta^2 - 2 \sin^2 \beta / \beta^3] = 0$ and this we have to equate to 0 and after simplification we will get $dI / d\beta = 2 I_0 \sin \beta / \beta^2 [\beta \cos \beta - \sin \beta] = 0$.

(Refer Slide Time: 17:29)

Either $\sin \beta = 0 \Rightarrow \beta = m\lambda (m \neq 0)$, this correspond to minima.

The conditions for maxima are roots of the equation

$$\beta \cos \beta - \sin \beta = 0$$

Or $\beta = \tan \beta$

The roots of this equation can be found by determining the points of intersections of the curves $Y = \beta$ and $Y = \tan \beta$ as shown in this diagram. The intersections occur at $\beta = 0, \beta = 1.43 \pi, \beta = 2.46 \pi$ etc. The root $\beta = 0$ corresponds to the central maximum.

For this we have $I = I_0 \frac{\sin^2 \beta}{\beta^2} = I_0$

So, here either $\sin \beta = 0$ this will gives $\beta = m \lambda$ where m is not is $= 0$ this corresponds to minimum intensity. The condition for maxima are roots of the equation $\beta \cos \beta - \sin \beta = 0$ or $\beta = \tan \beta$.

(Refer Slide Time: 17:53)

The roots of this equation can be found by determining the position of intersections of the curves $Y = \beta$ and $y = \tan \beta$ as shown in this diagram. The intersections occur at $\beta = 0$ and $\beta = 1.43 \pi$ and $\beta = 2.46 \pi$ by etc. The root $\beta = 0$ corresponds to the central maxima and for this we have $I = I_{\text{naught}}$. The other roots like $\beta = 1.43 \pi$, $\beta = 2.46 \pi$ etc give the position of first Maxima, second Maxima so on.

So intensity of principal Maxima as we have seen is given by $I = I_{\text{naught}}$. So, for the first Maxima we have $\beta = 1.43 \pi$, so putting this value of β in the intensity equation.

(Refer Slide Time: 19:08)

The other roots $\beta = 1.43 \pi$, $\beta = 2.46 \pi$ etc give the positions of first maxima, second maxima, etc.

Intensity of principal Maxima $I = I_0$.

For first Maxima we have $\beta = 1.43 \pi$. Putting this value of β in the intensity equation, we get intensity of first maxima.

$$\text{Intensity first maxima } I = I_0 \left[\frac{\sin(1.43 \pi)}{1.43 \pi} \right]^2$$

$$I = 0.0496 I_0$$

We get the intensity of first Maxima = $I_0 \left(\frac{\sin 1.43 \pi}{1.43 \pi} \right)^2$.
So, this comes out to be 0.0496 I_0 .

(Refer Slide Time: 19:32)

Thus, intensity of the First Maximum is about 4.96% of the central maximum.

Similarly Intensity of the second maxima is 1.68% of the principal maxima I_0 .

Thus, the Intensity of the principal maxima is about 20 times as great as that of the first secondary maxima. Secondary maxima are very feeble and their intensities diminish very rapidly as shown in this figure.

Thus the intensity of the first Maxima is about 4.96% of the central maximum.

(Refer Slide Time: 19:39)

Similarly intensity of second Maxima is 1.68% of the principle Maxima I_0 . Thus the intensity of the principal Maxima is about 20 times as great as that of the first secondary maximum. Secondary Maxima are very feeble and their intensities given is very rapidly as shown in this figure.

(Refer Slide Time: 20:09)

Order of Maxima	β	I/I_0
0	0	1
1	1.430	0.0469
2	2.459	0.0168
3	3.471	0.0083
4	4.477	0.0050
5	5.482	0.0034
6	6.484	0.0024

This table shows the relative intensity I/I_0 of different maxima. We can see here that most of the light is concentrated in the central maxima.

This table describes the intensity of various secondary maxima and from here we can again see that most of the light is concentrated only in the principal Maxima. Now let us find the width of the principal Maxima.

(Refer Slide Time: 20:33)

Order of Maxima	β	I/I_0
0	0	1
1	1.430	0.0469
2	2.459	0.0168
3	3.471	0.0083
4	4.477	0.0050
5	5.482	0.0034
6	6.484	0.0024

This table shows the relative intensity I/I_0 of different maxima. We can see here that most of the light is concentrated in the central maxima.

So, we have $\beta = \pi b \sin \theta / \lambda$ and for first minima β should be $+\pi$ or $-\pi$ or $\pi b \sin \theta / \lambda = +\pi$ from here we have $\sin \theta = +\lambda / b$ where b is the width of the slit.

(Refer Slide Time: 21:04)

\Rightarrow Spread of the principal maxima is inversely proportional to the width of the slit b .

If $\rightarrow b = \lambda$, then $\sin \theta = \pm 1$

$$\Rightarrow \theta = \pm \frac{\pi}{2}$$

That is the first minimum occurs at 90° with the normal. Under this condition, the light after traversing the slit spreads out in all directions, with an intensity which decreases steadily as θ increases. There are no maxima and minima.

So, from this equation we see that the spread of the principal Maxima is inversely proportional to the width of the slit b . If we take $b = \lambda$ then $\sin \theta$ will be $= \pm 1$ & $\theta = \pm \frac{\pi}{2}$ that is the first minimum occur at 90° with the normal. Under this condition the light after traversing the slit is spread out in all directions with an intensity which decreases steadily as θ increases there are no maxima and minima.

(Refer Slide Time: 21:48)

\rightarrow If $b < \lambda$, then for first minimum

$$b \sin \theta = \pm \lambda$$

$$\sin \theta = \pm \frac{\lambda}{b} > 1$$

Which is impossible.

Therefore $I = I_0 \left(\frac{\sin^2 \beta}{\beta^2} \right)$ does not hold when the slit width ' b ' becomes less than one- wavelength.

Further, if θ is very small, then $\sin \theta \approx \theta$.

If we take $b < \lambda$ then first then for first minimum $b \sin \theta$ should be $= \pm \lambda$ and $\sin \theta = \pm \frac{\lambda}{b}$ which will be greater than 1 if b is less than λ which is impossible. Therefore $I = I_0 \frac{\sin^2 \beta}{\beta^2}$ does not hold when

the slit width b becomes less than 1 wavelength. Further if θ is very small we can write $\sin \theta \approx \theta$.

(Refer Slide Time: 22:27)

So, half-width of the principal maxima, $\Delta\theta \sim \lambda/b$.

In the limit of $\lambda \rightarrow 0$, $\Delta\theta \rightarrow 0$ and the diffraction effects will be completely absent.

\Rightarrow Here it should be noted that the spreading is only in the direction of the width of the slit, not in the direction of length of the slit. This is because of the fact that the length of the slit is very large compared to its width.

So, half width of the principal maximum $\Delta\theta$ will be approximately $= \lambda/b$ in the limit of λ tending to 0 $\Delta\theta$ will be tending to 0 and the deflection effect will be completely absent. Here it should be noted that the spreading is only in the direction of the width of the slit not in the direction of length of the slit. This is because of the fact that length of the slit is very large compared to its width.

(Refer Slide Time: 23:12)

Thus, when a beam of parallel monochromatic light is incident normally on a opaque plate in which there is a long narrow slit, the transmitted beam spreads out in a direction perpendicular to the length of the slit. So, when it is focused on the screen by a lens, single slit diffraction pattern is observed, which consists of central bright band, much wider than the slit width, situated directly opposite to the slit and bordered by dark and bright bands of decreasing intensity. The central bright band is extremely intense and its width is twice as great as that of fainter side bands.

Thus when a beam of parallel monochromatic light is incident normally on a opaque plate in which there is a long narrow slit the transmitted beam is spread out in a direction perpendicular to the length of the slit. So, when it is focused on this screen by a lens single slit diffraction pattern is observed which consists of central bright band much wider than the slit width situated directly opposite to the slit and bordered by dark and bright bands of decreasing intensity.

The central bright band is extremely intense and its width is approximately twice as great as that of inter site band. So, this finishes the description of single slit diffraction patterns. And now I will discuss the diffraction at a circular aperture.

(Refer Slide Time: 24:11)

So, if we replace single slit as we have discussed in previous discussion by a circular aperture then the diffraction pattern is consisted of a bright disc called Harris ring, Harris disc surrounded by a number of concentric alternate dark and bright rings of rapidly decreasing intensity as shown in this figure. I will not discuss here the detailed theory of diffraction at circular aperture.

But on the basis of theoretical calculation it assume that the angular radius of the first dark ring is 1.22λ by d where d is the diameter of the circular aperture and λ is the wavelength of the monochromatic light. This may also be taken as the angular radius of the bright central disc about 84% of the transmitted light energy is concentrated in the central bright disc. This result we will use later to calculate the resolving power of telescope and microscopes.

(Refer Slide Time: 25:41)

So, now let us discuss the diffraction pattern of double slit so here let us consider two parallel slits each of width b and separated by a opaque region of width a has shown in this figure. Now we will study in the diffraction pattern produced by two slits when a beam of monochromatic light of wavelength λ is incident normally on the plane of the slits. Like single slit let us consider that both slit consists of a large number of equally spaced point sources.

And that each point on the slit is his source of Huygens secondary wavelets. Let the point sources be at A_1, A_2, A_3 etc in the first slit and V_1, V_2, V_3 etcetera in the second slit. We assume that the distance between the two consecutive points in either of the slit is $d = a + b$, if the deflected rays make an angle θ when the normal to the plane of the slit then the path difference between the disturbance reaching the point P on the screen from two consecutive points in a slit it will be $d \sin \theta$.

(Refer Slide Time: 27:14)

$$E_1 = A \frac{\sin \beta}{\beta} \cos(\omega t - \beta)$$

Similarly, the second slit will produce a field

$$E_2 = A \frac{\sin \beta}{\beta} \cos(\omega t - \beta - \phi) \quad \text{at the point P,}$$

$$\text{where } \phi = \frac{2\pi}{\lambda} (a + b) \sin \theta$$

$$\phi = \frac{2\pi}{\lambda} d \sin \theta$$

where $d = a + b$.

Φ represents the phase difference between the disturbances (reaching the point P) from two corresponding point on the slits; by corresponding points we imply pairs of points like $(A_1, B_1), (A_2, B_2), \dots$ on the slits which are separated by a distance $d = a + b$.

The field produced by the first slit at the point P will therefore be given by $E_1 = a \sin \beta \cos \omega t - \beta$, similarly the second slit will produce a field $E_2 = a \sin \beta \cos \omega t - \beta - \Phi$ at the point P where $\Phi = \frac{2\pi}{\lambda} (a + b) \sin \theta$ or $\Phi = \frac{2\pi}{\lambda} d \sin \theta$ where $d = a + b$. Φ represent the phase difference between the disturbance reaching the point P from two corresponding point on the slit.

By corresponding points we imply pair of points like A_1, B_1, A_2, B_2 so on. On the slit which are separated by a distance $d = a + b$.

(Refer Slide Time: 28:14)

Therefore, the resultant field at P will be

$$\begin{aligned} E &= E_1 + E_2 \\ &= \frac{A \sin \beta}{\beta} \cos(\omega t - \beta) + \frac{A \sin \beta}{\beta} \cos(\omega t - \beta - \phi) \\ &= \frac{A \sin \beta}{\beta} [\cos(\omega t - \beta) + \cos(\omega t - \beta - \phi)] \\ &= 2A \frac{\sin \beta}{\beta} \cos \frac{\phi}{2} \cos \left[\omega t - \beta - \frac{\phi}{2} \right] \end{aligned}$$

$$\text{If } \gamma = \frac{\phi}{2} = \frac{\pi}{\lambda} d \sin \theta.$$

$$E = 2a \frac{\sin \beta}{\beta} \cos \gamma \cos[\omega t - \beta - \gamma]$$

Therefore the resultant field at P will be $= E_1 + E_2$ and so now substituting the value of E_1 and E_2 we get the resultant field at the point P, $E = 2a \sin \beta \cos \frac{\phi}{2} \cos \Omega t - \beta - \frac{\phi}{2}$ if we define $\gamma = \frac{\phi}{2} = \frac{\pi}{\lambda} (a + b) \sin \theta$ then the resultant field $E = 2a \sin \beta \cos \gamma \cos \Omega t - \beta - \gamma$.

(Refer Slide Time: 29:09)

So the intensity of the resultant field at P will be

$$I = 4A^2 \frac{\sin^2 \beta}{\beta^2} \cos^2 \gamma$$

$$A^2 = I_0$$

$$I = 4I_0 \frac{\sin^2 \beta}{\beta^2} \cos^2 \gamma, \quad \gamma = \frac{\pi}{\lambda} (a + b) \sin \theta, \quad \beta = \frac{\pi}{\lambda} b \sin \theta$$

So, the intensity of the resultant field at P $= 4A^2 \sin^2 \beta \cos^2 \gamma$ divided by β^2 into $\cos^2 \gamma$. Here $A^2 = I_0$ then I will be $= 4I_0 \sin^2 \beta \cos^2 \gamma$ where $\gamma = \frac{\pi}{\lambda} (a + b) \sin \theta$ and $\beta = \frac{\pi}{\lambda} b \sin \theta$.

(Refer Slide Time: 29:47)

where $I_0 \frac{\sin^2 \beta}{\beta^2}$ represent the intensity distribution produced by one of the slits. The intensity distribution is a product of two terms; the first term $\frac{\sin^2 \beta}{\beta^2}$ represent the diffraction pattern produced by a single slit of width b and the second term $\cos^2 \gamma$ represents the interference pattern produced by two point sources separated by a distance $(a + b)$. If the slit width are very small (so that there is almost no variation of the term $\frac{\sin^2 \beta}{\beta^2}$ with θ) then we simply obtain the young's interference pattern.

So, this equation described the intensity of double slit diffraction pattern on the screen in this expression $I \propto \sin^2 \beta / \beta^2$ represent the intensity distribution produced by one of the slit. The intensity distribution is a product of two terms the first term $\sin^2 \beta / \beta^2$ represent the diffraction pattern produced by a single slit of width b and the second term $\cos^2 \gamma$ represent the interference pattern produced by two point sources separated by a distance $a + b$.

If the slit width are very small, so that there is almost no variation of terms $\sin^2 \beta / \beta^2$ with θ then we simply obtain the Young's interference pattern.

Dependence of Intensity on $I_0 \frac{\sin^2 \beta}{\beta^2}$

The intensity I is Zero, whenever this function vanishes, that is when

$\sin \beta = 0 \Rightarrow \beta = \pm m\pi$, where $m = 1, 2, 3, \dots, m \neq 0$

or $b \sin \theta = \pm m\lambda$

Now let us discuss the dependence of intensity on $I \propto \sin^2 \beta / \beta^2$ term that is single slit intensity pattern. The intensity I is 0 whenever this function vanishes that is when $\sin \beta = 0$ that is $\beta = \pm m\pi$ where $m = 1, 2, 3$ but m is not 0 or $b \sin \theta = \pm m\lambda$. So, whenever this condition is satisfied the intensity of intensity in the diffraction pattern or double slit will be 0.

(Refer Slide Time: 31:50)

The positions of maxima, due to this factor are at $\beta = 0$ and at values of β approaching to

$$\pm \frac{3\pi}{2}, \pm \frac{5\pi}{2}, \pm \frac{7\pi}{2} \text{ etc.}$$

Dependence of intensity on $\cos^2 \gamma$:-

The position of maximum intensity due to this factor are given by those values of γ for which $\cos^2 \gamma = 1$.

$$\gamma = \frac{\pi}{\lambda}(a+b)\sin\theta$$

$$\gamma = \pm n\pi \quad (n = 0, 1, 2, 3, \dots)$$

$$(a+b)\sin\theta = \pm n\lambda \quad (n = 0, 1, 2, 3, \dots) \text{ For Maxima}$$

Now the position of Maxima due to this factor are at $\beta = 0$ and at value of β approaching to $\pm 3\pi/2, \pm 5\pi/2, \pm 7\pi/2$ etc. Now let us discuss the dependence of intensity on $\cos^2 \gamma$ term. The position of maximum intensity due to this factor are given by those value of γ for which $\cos^2 \gamma = 1$ or where $\gamma = \pi/2, 3\pi/2, 5\pi/2, 7\pi/2$ etc. So, $\cos^2 \gamma$ will be 1 when $\gamma = \pm n\pi$ where $n = 0, 1, 2, 3$ so on or $(a+b)\sin\theta = \pm n\lambda$.

Again $n = 0, 1, 2, 3$ this is the condition for maximum intensity in double slit diffraction pattern.

(Refer Slide Time: 33:02)

The points separated by a distance $(a+b)$ in the two slits are known as corresponding points. The conditions for maxima given by above equation simply states that for maxima, the path difference between the parallel diffracted ray from any pair of corresponding points in the – slits should be even multiple of $\lambda/2$.

The whole number n represents the order of interference maximum.

The position of zero intensity in the interference pattern are given by those values of γ which satisfy

So, the point separated by distance $a + b$ in the 2 slits are known as corresponding points. So, the condition for Maxima given by the above equation simply states that for Maxima the path difference between the parallel refracted ray from any pair of corresponding point in the slit should be even multiple of λ by 2. The whole number n represents the order of interference maximum. The positions of 0 intensity in the interference pattern are given by those values of γ .

(Refer Slide Time: 33:46)

$$\cos^2 \gamma = 0, \text{ that is } \gamma = \pm(2n+1)\frac{\pi}{2} = \pm\left(n + \frac{1}{2}\right)\pi$$

Thus minima occur at angle θ , such that

$$(a+b) \sin \theta = \pm\left(n + \frac{1}{2}\right)\lambda \text{ or } (a+b) \sin \theta = \pm(2n+1)\frac{\lambda}{2} \text{ (Minima)}$$

Or $d \sin \theta = \pm\left(n + \frac{1}{2}\right)\lambda \quad n = 0, 1, 2, \dots$

This equation simply expresses the condition that for minima, the path difference between the parallel diffracted rays from any pair of corresponding points in the two slits should be odd multiple of $\frac{\lambda}{2}$ on the reaching the focal plane of the focusing lens.

Which satisfy $\cos^2 \gamma = 0$ that is in $\gamma = \pm n + \frac{1}{2}\pi$, thus the minimum occur at angle θ such that $a + b \sin \theta = \pm n + \frac{1}{2}\lambda$ or $d \sin \theta = \pm n + \frac{1}{2}\lambda$ where $n = 0, 1, 2, 3$. This equation simply expresses the condition that for minima the path difference between the parallel deflected rays from any pair of corresponding point in two slits should be all odd multiple of λ by 2 on reaching the focal plane of the focusing lens.

Missing orders of Interference maxima

If the slit width 'b' is kept constant and the separation between them, i.e. 'd' is varied, then from the equation

$$(a + b) \sin \theta = \pm n\lambda$$

it is obvious that the distance between two consecutive interference maxima varies and the size of diffraction pattern due to single slit remains constant. A study of the resultant diffraction pattern so obtained reveals that certain orders of interference maxima are missing.

Now let us discuss the missing order of interference Maxima in the double slit diffraction pattern if the slit width b is kept constant and the separation between them that is d is varied then from the equation $a + b \sin \theta = + - 1 n \lambda$. It is obvious that the distance between two consecutive interference Maxima varies and the size of diffraction pattern due to single slit remains constant.

A study of the resultant diffraction pattern so obtained revealed that certain orders of interference Maxima are missing.

(Refer Slide Time: 35:34)

Let us suppose that for same value of θ , the following relations are simultaneously hold good

$$b \sin \theta = \pm m \lambda$$

$$(a + b) \sin \theta = \pm n \lambda$$

The first equation expresses the condition for zero intensity in the single slit diffraction while the second equation expresses the condition for a maximum in the interference pattern. Therefore, the interference maxima will be absent in this direction θ .

From above equations, we get

$$\frac{a + b}{b} = \frac{n}{m}$$

Let us suppose that for the same value of theta the following relations are simultaneously hold good, $b \sin \theta = + - m \lambda$ and $a + b \sin \theta = + - n \lambda$. The first equation expressed says the condition for 0 intensity in the single slit diffraction while the second equation expresses the condition for a maximum in the interference pattern therefore the interference Maxima will be absent in this direction theta. From the above equations we can write $a + b$ divided by $b = n$ by m .

(Refer Slide Time: 36:26)

Since n and m are integral numbers, the ratio $\frac{a+b}{b}$ should be the ratio of two integers for missing orders.

The ratio $\frac{(a+b)}{b}$ determines the orders of the missing interference maxima. For example, if

$$\frac{(a+b)}{b} = 2, \quad n = 2m \quad \text{Now, giving } m \text{ integral values}$$

we get the corresponding values of missing order n .

$$m = 1, 2, 3, 4, 5 \text{ etc}$$

$$n = 2, 4, 6, 8, 10 \text{ etc.}$$

Since n and m are integral numbers that is ratio $a + b$ by b should be the ratio of two integers for missing order. The ratio $a + b$ by b determines the order of the missing interference Maxima. For example if $a + b$ by $b = 2$ then n will be $= 2$ times m . Now giving the m integral values we get the corresponding values of missing order n . So, if we have $m = 1, 2, 3, 4, 5$ etc then $n = 2, 4, 6, 8, 10$ etcetera.

(Refer Slide Time: 37:12)

Thus, there will be three interference maxima within the central diffraction maximum.

ii) $\frac{(a+b)}{b} = 3$, Then $n = 3m$ therefore, when
 $m = 1, 2, 3, 4, 5 \text{ etc}$

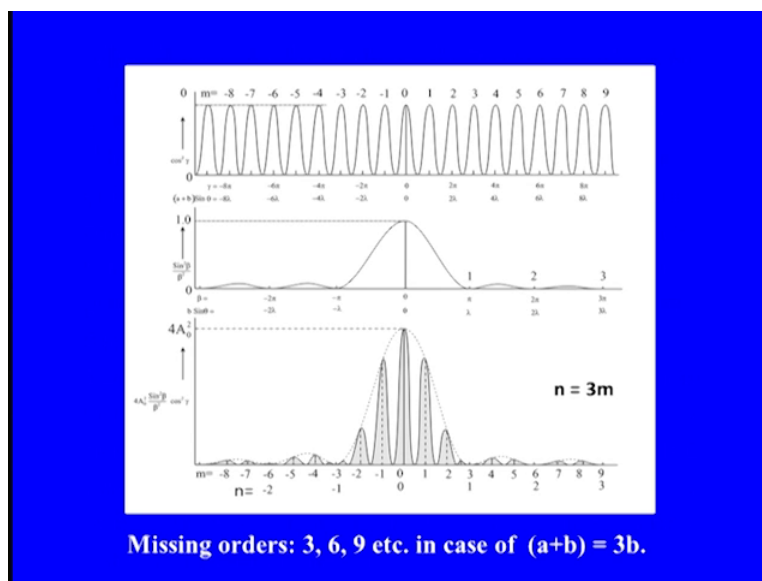

Missing order $n = 3, 6, 9, 12, 15 \text{ etc.}$

Thus, there will be five interference maxima within the central diffraction maximum. In this way, as the ratio $\frac{d}{b}$ increases, the number of interference maxima within the central diffraction maximum also increases.

Thus there will be 3 interference Maxima within the central diffraction Maxima. Similarly if we have $a + b$ by $b = 3$ then n will be $= 3$ times m . Therefore when $m = 1, 2, 3, 4, 5$ etc then n will be $= 3, 6, 9, 12, 15$ etc and this value of n correspond to missing order so, thus there will be 5 interference Maxima within the central diffraction maximum.

In this way either ratio d by b increases the number of interference maxima within the central diffraction maximum also increases. The physical explanation of missing order is as follows.

(Refer Slide Time: 38:23)

Consider for an example the missing order $n = 2$ the point on the screen where we expect this order is just 2λ further from the center of one slit than from the center of the other. But

since slit width is same as opaque region between slit this point is one wavelet further from one edge than the other edge of the same slit. Consequently the secondary wavelets from this slit produce zero intensity at this point. The same is true for the second slit.

Thus it is obvious that the resultant intensity at this point due to the resultant of each slit will be 0 that is the second order maximum will be absent. This figure shows the intensity curve for double slit diffraction for the case $a + b = 3 \text{ times } b$ and explain the missing order 3, 6, 9, etc in the diffraction pattern. So, let me summarize what we have discussed till now in this lecture. So, first I explained what is diffraction and then I explained the diffraction pattern of single slit.

So, there I we saw that in the single slit diffraction pattern we have a central maxima where almost all light incident light is confined and this central maxima is surrounded by many secondary Maxima of decreasing intensity. Then I describe the double slit diffraction patterns so in the double slit diffraction pattern is the determined by two terms. First term is the single slit diffraction pattern and then there is a interference term coming in the final expression which describe the intensity pattern of double slit diffraction patterns, thank you.
