Lecture - 1
Solution of Ode of First Order and First Degree

Dear viewers, I am Dr. P. N. Agrawal professor in Department of Mathematics, IIT, Roorkee. In my lecture, I am going to discuss the various methods of obtaining a general solution of ordinary differential equation of first order and first degree.

(Refer Slide Time: 00:51)

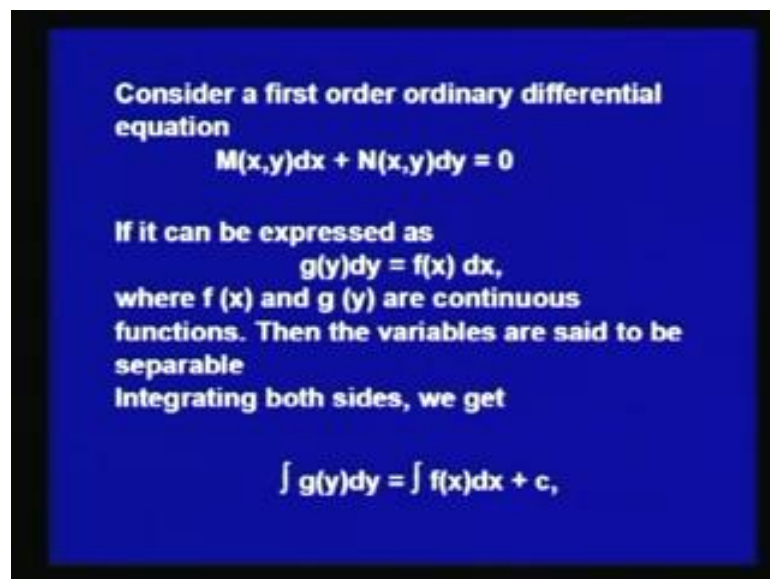

In ordinary differential equation of first order and first degree can be solved by standard methods, if it belongs to one of the following categories or can be reduced to any one of them. First equations in which variables are separable, second in homogeneous equations, third exact equations, fourth is linear equations. All other differential equations are first order and first degree, which do not belong to any one of those categories can be solved using numerical methods, which give us an approximate solution of the given differential equation. We shall talk about approximate methods, which gives us solutions of those differential equations later on. First we shall discuss those differential equations where, which can be solved analytically, so we begin with equations in which variables are separable.

(Refer Slide Time: 01:51)

Equations reducible to separable form.

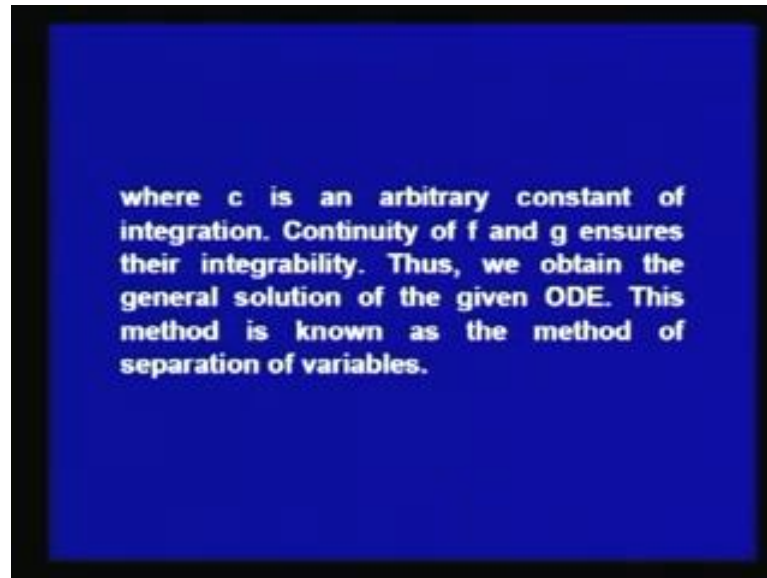

(Refer Slide Time: 01:52)

Let us begin with a ordinary differential equation of first order in first degree, it can be expressed as $M dx + N dy = 0$ where M and N are functions of x and y . Now, if we are able to express it in the form $g(y) dy = f(x) dx$, where $g(y)$ is the function of y only and $f(x)$ is the function of x only and $f(x)$ and $g(y)$ are continuous functions. Then we say that the given differential equation belongs to the category of those differential equations where variables are separable.

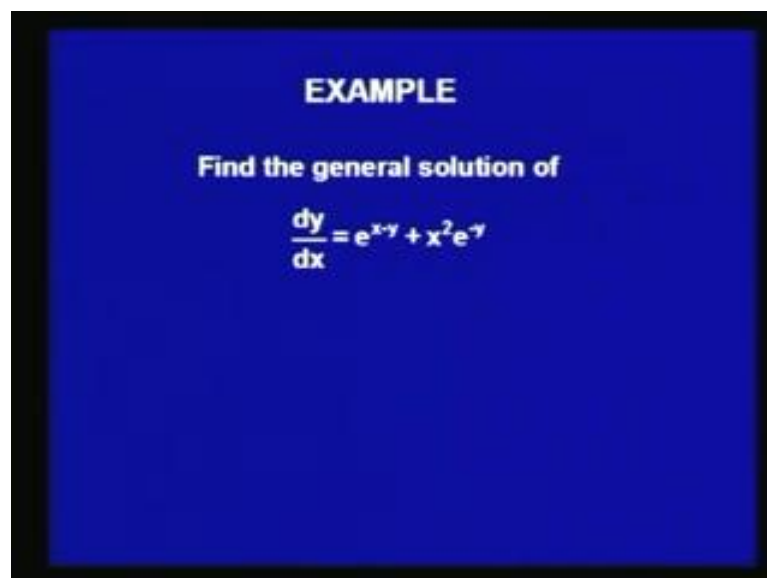

General solution of such a differential equation can be obtained very easily, we just have to integrate both sides of the given differential equation and we have $\int g(y) dy$ equal to $\int f(x) dx + c$.

(Refer Slide Time: 02:45)

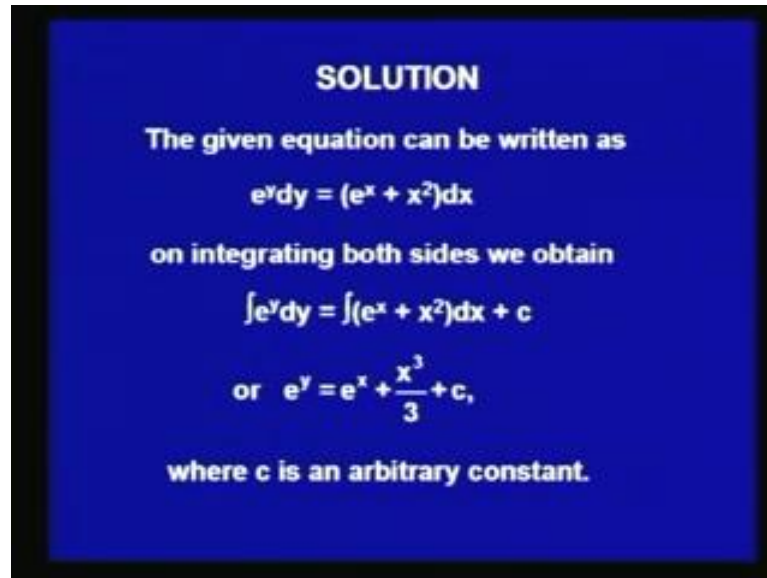

Where c is an arbitrary constant of integration, since f and g are continuous functions they are integrable. So, the integral of f and integral of g axis can be obtained the general solution of the given ordinary differential equation, this method is known as the method of separation of variables.

(Refer Slide Time: 03:07)

Let us consider an example of a first order ordinary differential equation of a degree, which belongs to this category of variable separable form. Let us take $\frac{dy}{dx}$ equal to $e^y - x + x^2$.

(Refer Slide Time: 03:31)

SOLUTION

The given equation can be written as

$$e^y dy = (e^x + x^2) dx$$

on integrating both sides we obtain

$$\int e^y dy = \int (e^x + x^2) dx + c$$

or $e^y = e^x + \frac{x^3}{3} + c,$

where c is an arbitrary constant.

Now, this differential equation can be written as $e^y \frac{dy}{dx} = e^x - x + x^2$, when do you multiply the given differential equation by e^y and then by dx we arrive at this equation. And we can know that on the left side we have a function of y only, while on the right side we have a function of x only. And therefore, when we integrate both sides of this differential equation, we have $\int e^y dy = \int (e^x - x + x^2) dx + c$; or we will have $e^y = e^x - \frac{x^2}{2} + \frac{x^3}{3} + c$, where c is an arbitrary constant.

(Refer Slide Time: 04:20)

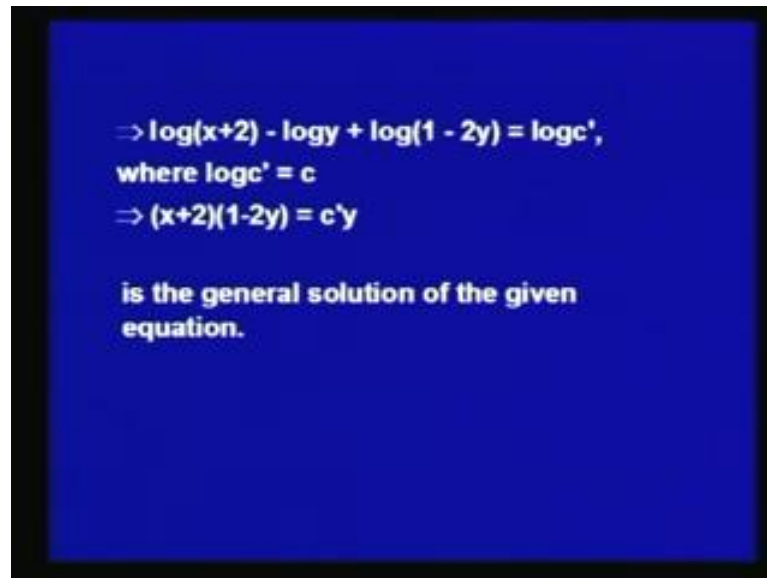

EXAMPLE:
Solve $y - x \frac{dy}{dx} = 2 \left(y^2 + \frac{dy}{dx} \right)$

SOLUTION:
The given equation can be written as
$$y(1-2y) - (x+2) \frac{dy}{dx} = 0$$
$$\frac{dx}{x+2} - \frac{dy}{y(1-2y)} = 0$$

Integrating both sides, we have
$$\int \frac{dx}{x+2} - \int \left(\frac{1}{y} + \frac{2}{1-2y} \right) dy = c$$

Let us take up another problem, which is y minus x into $d y$ by $d x$ equal to 2 times y square plus $d y$ by $d x$, now this equation can be rewritten as y into 1 minus $2 y$ minus x plus 2 into $d y$ by $d x$ equal to 0 . Or we may write it as $d x$ over x plus 2 minus $d y$ over y into 1 minus $2 y$ equal to 0 , now you can see that the variables x and y have again being separated. First term is a function of x only, while the second term is a function of y only and with this equation again belongs to the case of differential equations where the variables are separable. We integrate both sides and get integral $d x$ over x plus 2 minus integral of 1 over y plus 2 over 1 minus $2 y$ $d y$ equal to c . Here we have the broken we term 1 over y into 1 minus $2 y$ into partial fractions, the partial fractions are 1 over y plus 2 over 1 minus $2 y$.

(Refer Slide Time: 05:35)

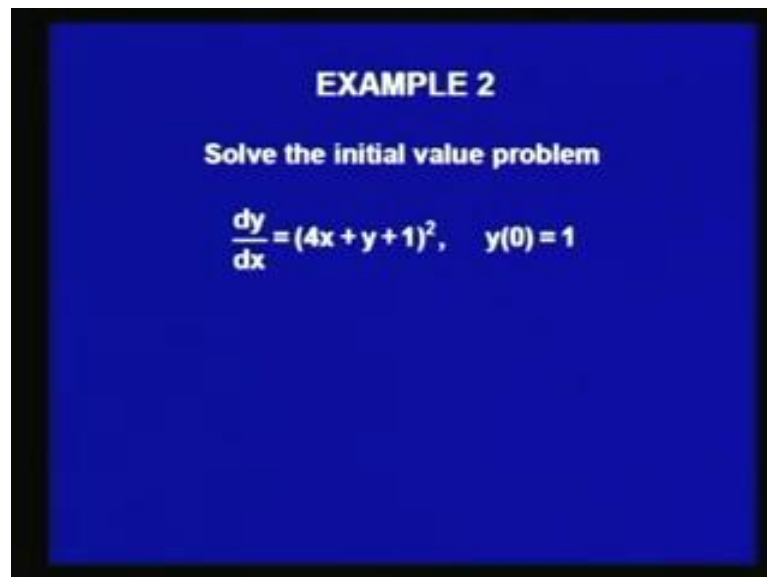

$\Rightarrow \log(x+2) - \log y + \log(1 - 2y) = \log c'$,
where $\log c' = c$
 $\Rightarrow (x+2)(1-2y) = c'y$

is the general solution of the given equation.

Now, after integration we get log of x plus 2 minus log y plus log 1 minus 2 y equal to log c dash, where we define log c dash equal to c. This will give us x plus 2 into 1 minus 2 y equal to c dash y, which is then the general solution of the given differential equation.

(Refer Slide Time: 05:57)

EXAMPLE 2

Solve the initial value problem

$$\frac{dy}{dx} = (4x + y + 1)^2, \quad y(0) = 1$$

Now, let us consider the initial value problem $\frac{dy}{dx} = 4x + y + 1$ whole square where $y(0) = 1$. And initial value problem is 1, where the value of the given depended variable y is given at an initial value of x, that is x equals to 0.

(Refer Slide Time: 06:20)

SOLUTION

The given differential equation can be reduced to the 'variable separable' form by putting $4x + y + 1 = t$ which yields

$$\frac{dy}{dx} = \frac{dt}{dx} - 4$$

So, the given equation becomes

$$\frac{dt}{dx} - 4 = t^2 \text{ or } \frac{dt}{4 + t^2} = dx$$

In the case of this differential equation, we substitute $4x + y + 1 = t$, in order to bring it to the variable separable form, because then dy by dx will be equal to dt by dx minus 4. And so we will be getting the given equation in the form dt by dx minus 4 equal to t square or dt by $4 + t$ square equal to dx . You can see now the variables x and t have been separated on the left hand side we have a function of t only, and on the right hand side we have a function of x .

(Refer Slide Time: 06:59)

Integrating both sides, we get

$$\frac{1}{2} \tan^{-1} \frac{t}{2} = x + c$$

or

$$\frac{1}{2} \tan^{-1} \left(\frac{1}{2}(4x + y + 1) \right) = x + c$$

The initial condition

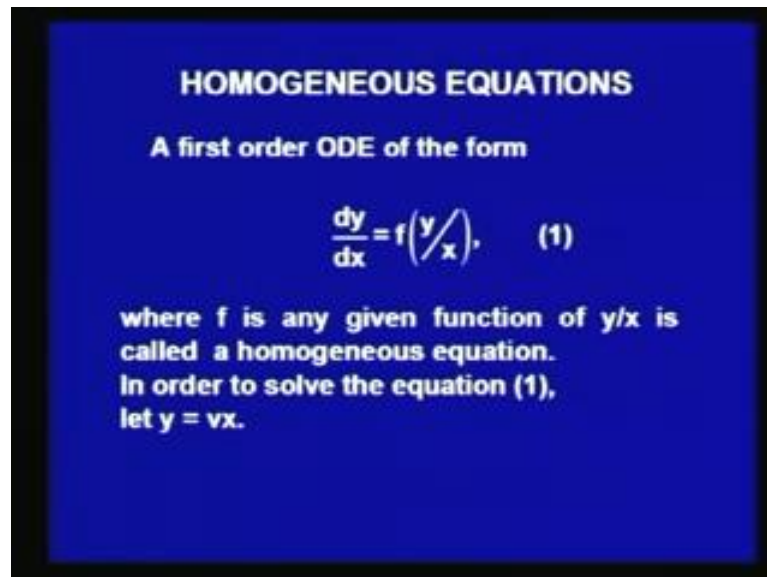

$$y(0) = 1 \Rightarrow c = \frac{\pi}{8}$$

Hence the solution is

$$4x + y + 1 = 2 \tan \left(2x + \frac{\pi}{4} \right).$$

So, after integrating those sides we get half of tan inverse t by 2 equal to x plus c, which is equal to half tan inverse half 4 x plus y plus 1 equal to x plus c. Now, when we make use of the initial condition y 0 equal to 1, we get c equal to phi by 8 and thus the solution is 4 x plus y plus 1 equal to 2 tan 2 x plus phi by 4.

(Refer Slide Time: 07:31)

HOMOGENEOUS EQUATIONS

A first order ODE of the form

$$\frac{dy}{dx} = f\left(\frac{y}{x}\right), \quad (1)$$

where f is any given function of y/x is called a homogeneous equation.
In order to solve the equation (1),
let $y = vx$.

Let us now take up another case of differential equations, ordinary differential equations of first order first degree, that is homogeneous equations. If a first order ordinary differential equation of first degree is of the form $\frac{dy}{dx} = f\left(\frac{y}{x}\right)$, where f is any given function of y over x . We shall call such a differential equation as a homogeneous equation, in order to solve such a differential equation we put y equal to v into x .

(Refer Slide Time: 08:06)

Then we have

$$\frac{dy}{dx} = v + x \frac{dv}{dx}$$

on substituting in (1), we have

$$v + x \frac{dv}{dx} = f(v)$$

or $\frac{dv}{f(v) - v} = \frac{dx}{x}$.

Integrating both sides and replacing v by y/x , we obtain the general solution of (1).

Then dy by dx will be equal to v plus x dv by dx and when we substitute it in the equation 1, we shall have v plus x dv by dx equal to $f(v)$ or we can separate the variables x and v and get dv over $f(v) - v$ equal to dx over x . Now, we can integrate both sides of this differential equations and then replace v by y over x to obtain the general solution of the given differential equation.

(Refer Slide Time: 08:40)

EXAMPLE

solve $(1+2e^{xy})dx + 2e^{xy}(1-\frac{x}{y})dy = 0$

SOLUTION

$$\frac{dy}{dx} = -\frac{(1+2e^{xy})}{2e^{xy}(1-\frac{x}{y})}$$

Let $y = vx$ then

$$\frac{dy}{dx} = v + x \frac{dv}{dx} \text{ and}$$

so $v + x \frac{dv}{dx} = -\frac{(1+2e^{1v})}{2e^{1v}(1-\frac{1}{v})}$

Let us take an example of a differential equation belonging to this type, let us consider 1 plus 2 times e to the power x over y dx plus 2 time e to the power x over y into 1 minus

x over y dy equal to 0. You can see here, that this differential equation may be written as dy by dx equal to minus 1 plus 2 times e to the power x over y divided by 2 times e to the power x over y into 1 minus x over y . The right hand side of this equation is the function of y over x , so let us put y equal to $v x$, then we shall have v plus x dv by dx equal to minus 1 plus 2 times e to the power 1 over v divided by 2 times e to the power 1 over v into 1 minus 1 over v .

(Refer Slide Time: 09:35)

$$x \frac{dv}{dx} = -\frac{(1+2e^{1/v})}{2e^{1/v}(1-\frac{1}{v})} - v$$

$$= \frac{-1-2e^{1/v}-2ve^{1/v}+2e^{1/v}}{2e^{1/v}(1-\frac{1}{v})}$$

$$\int \frac{2e^{1/v}(1-\frac{1}{v})dv}{2ve^{1/v}+1} = -\int \frac{dx}{x} + c$$

$$\text{or } \int \frac{2(e^{1/v} - \frac{1}{v}e^{1/v})dv}{2ve^{1/v}+1} = -\ln x + c$$

We can simplify this equation and get x into dv by dx equal to minus 1 plus 2 times e to the power 1 over v over 2 times e to the power 1 over v minus into 1 minus 1 over v minus v ; which will give us after simplification minus 1 minus 2 e to the power 1 over v minus 2 times v into e the power 1 over v plus 2 times e to the power 1 over v divided by 2 times e to the power 1 over v into 1 minus 1 over v .

Now, we can bring the variables v on 1 both side and the variable x on the other side and then integrate both sides. So, we shall have integral of 2 e to the power 1 over v into 1 minus 1 over v dv divided by $2v$ into e to the power 1 over v plus 1 equal to minus integral of dx over x plus c ; now the denominator $2v$ e to the power 1 over v plus 1 when we put equal to t .

(Refer Slide Time: 10:35)

Let $2ve^{1/v} + 1 = t$, then
 $2(e^{1/v} - \frac{1}{v}e^{1/v})dv = dt$ &
so $\int \frac{dt}{t} = -\log x + c$
 $\Rightarrow \log t = -\log x + c$
 $\Rightarrow \log(2ve^{1/v} + 1) = -\log x + c$
or $x(2ve^{1/v} + 1) = e^c = c' =$ a new arbitrary constant
or $(x + 2ye^{xy}) = c'$
is the general solution of the given ODE.

We note that we get the derivative as 2 times e to the power 1 over v minus 1 over v into e to the power 1 over v into d v equal to d t and so the equation becomes integral d t by t equal to minus log x plus c. The integration gives us log t equal to minus log x plus c or we may say log of 2 v into e to the power 1 over v plus 1 equal to minus log x plus c, which will further give x into 2 v e to the power 1 over v plus 1 equal to e to the power c. E to the power c can be written as a new arbitrary constant c dash and we shall then have x plus 2 y e to the power x over y equal to c dash when we put the value of v equal to y over x. So, this is the general solution of the given ordinary differential equation.

(Refer Slide Time: 11:30)

EXAMPLE:
Solve $xdy - ydx = \sqrt{x^2 + y^2}dx$

SOLUTION:
The given equation may be expressed as
$$\frac{dy}{dx} = \frac{y + \sqrt{x^2 + y^2}}{x} = \frac{y}{x} + \sqrt{1 + \frac{y^2}{x^2}} \quad (2)$$

Since the right hand side of the above equation is a function of y/x , the given differential equations is a homogeneous equation.

Now, let us consider the case of the differential equation $x \, dy - y \, dx = \sqrt{x^2 + y^2} \, dx$, this equation may be written as $\frac{dy}{dx} = \frac{y}{x} + \frac{\sqrt{1 + \frac{y^2}{x^2}}}{1}$. So, again we see that this differential equation is of the form $\frac{dy}{dx} = f\left(\frac{y}{x}\right)$ and hence, this differential equation is a homogeneous differential equation.

(Refer Slide Time: 12:12)

Putting $y = ux$ in (2) we have

$$u + x \frac{du}{dx} = u + \sqrt{1+u^2} \quad \text{or} \quad \frac{du}{\sqrt{1+u^2}} = \frac{dx}{x}$$

$$\Rightarrow \log \left(u + \sqrt{1+u^2} \right) = \log x + \log c$$

or $u + \sqrt{1+u^2} = cx$

or $\frac{y}{x} + \sqrt{1 + \frac{y^2}{x^2}} = cx$

$$\Rightarrow y + \sqrt{x^2 + y^2} = cx^2,$$

which is the required solution.

Now, so we will put y equal to $u x$ here and that will give us $u + x \frac{du}{dx} = u + \sqrt{1+u^2}$, we can separate the variables u and x and get $\frac{du}{\sqrt{1+u^2}} = \frac{dx}{x}$. When we integrate both sides, we get $\log \left(u + \sqrt{1+u^2} \right) = \log x + \log c$, so this will give us $u + \sqrt{1+u^2} = cx$. Let us put the value of u and we get $\frac{y}{x} + \sqrt{1 + \frac{y^2}{x^2}} = cx$, which then gives us the required solution as $y + \sqrt{x^2 + y^2} = cx^2$.

(Refer Slide Time: 12:57)

**NON-HOMOGENEOUS
EQUATIONS REDUCIBLE TO
HOMOGENEOUS FORM**

The differential equations of the form

$$\frac{dy}{dx} = \frac{ax+by+c}{a'x+b'y+c'} \quad (3)$$

can be solved as follows:

Now, we consider the case of non homogeneous equations, which are reducible to homogeneous form, the differential equations of the form $\frac{dy}{dx} = \frac{ax+by+c}{a'x+b'y+c'}$ can be solved as follows.

(Refer Slide Time: 13:18)

CASE I

When $\frac{a}{a'} \neq \frac{b}{b'}$

putting $x = X+h$ and $y = Y+k$, (h, k being constants)

we have

$$\frac{dY}{dX} = \frac{aX+bY+(ah+bk+c)}{a'X+b'Y+(a'h+b'k+c')}$$

Choose h & k such that $ah+bk+c=0$ & $a'h+b'k+c'=0$

First we take up the case where $\frac{a}{a'}$ is not equal to $\frac{b}{b'}$, so then we will put x equal to capital X plus h and y equal to capital Y plus k where h and k are some constants. And this substitution will give us $\frac{dY}{dX} = \frac{aX+bY+(ah+bk+c)}{a'X+b'Y+(a'h+b'k+c')}$.

Now, we will choose the constants h and k in such a way that $ah + bk + c = 0$ and $a'h + b'k + c' = 0$. If we do this, then the differential equation will reduce to homogeneous form.

(Refer Slide Time: 14:18)

then

$$h = \frac{bc' - b'c}{ab' - ba'}, \quad k = \frac{ca' - c'a}{ab' - ba'}$$

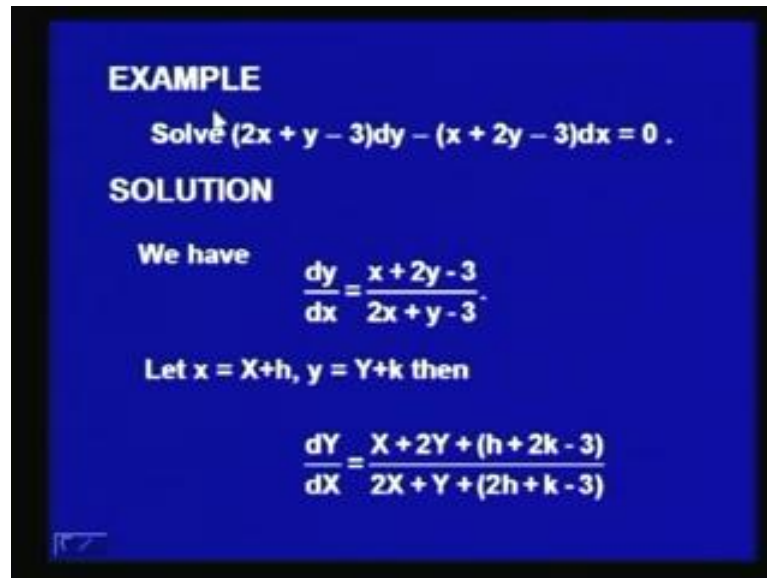

The equation (3) becomes

$$\frac{dY}{dX} = \frac{aX + bY}{a'X + b'Y}$$

which is homogeneous in X and Y and hence can be solved by putting $Y = vX$

The values of h and k can be obtained from the two linear equations involving h and k as $bc' - b'c$ over $ab' - ba'$ and k equal to $ca' - c'a$ over $ab' - ba'$. Now, since we have assumed that a' / a is not equal to b' / b , $ab' - ba'$ is not equal to 0 and therefore, h and k adjust. The equation (3) now becomes $dY/dX = (aX + bY) / (a'X + b'Y)$, which is a homogeneous equation in the variables capital X and capital Y and can then be solved by putting capital Y equal to v into capital X .

(Refer Slide Time: 14:56)

EXAMPLE
Solve $(2x + y - 3)dy - (x + 2y - 3)dx = 0$.

SOLUTION

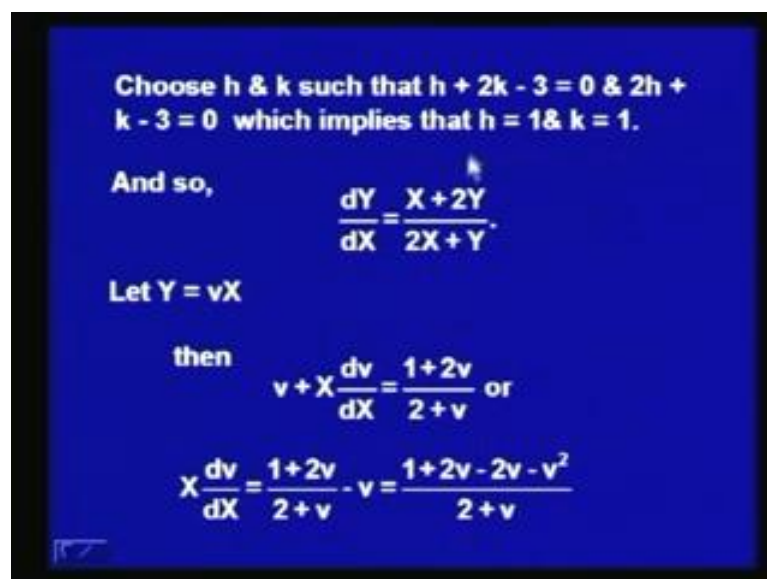

We have $\frac{dy}{dx} = \frac{x + 2y - 3}{2x + y - 3}$.

Let $x = X+h$, $y = Y+k$ then

$$\frac{dY}{dX} = \frac{X + 2Y + (h + 2k - 3)}{2X + Y + (2h + k - 3)}$$

Let us take an example of a differential equation of this category, suppose we consider the differential equation as $2x + y - 3$ into dy minus $x + 2y - 3$ dx equal to 0. We can write the given differential equation as dy by dx equal to $x + 2y - 3$ over $2x + y - 3$. And let us note that here a over a dash is half, while b over b dash is 2, so a over a dash is not equal to b over b dash. And therefore, we can put a small x equal to capital X plus h and small y equal to capital Y plus k to reduce it to homogeneous form. These substitutions will give us dY by dX equal to $X + 2Y + h + 2k - 3$ divided by $2X + Y + 2h + k - 3$.

(Refer Slide Time: 15:57)

Choose h & k such that $h + 2k - 3 = 0$ & $2h + k - 3 = 0$ which implies that $h = 1$ & $k = 1$.

And so, $\frac{dY}{dX} = \frac{X + 2Y}{2X + Y}$.

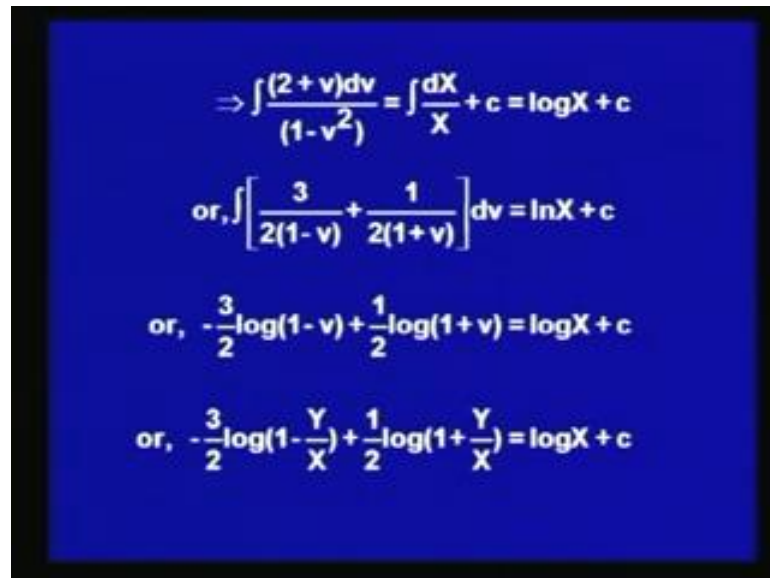

Let $Y = vX$

then $v + X \frac{dv}{dX} = \frac{1 + 2v}{2 + v}$ or

$$X \frac{dv}{dX} = \frac{1 + 2v}{2 + v} - v = \frac{1 + 2v - 2v - v^2}{2 + v}$$

Now, you will have to find h and k in such a way that, h plus 2 k minus 3 is equal to 0 and 2 h plus k minus 3 equal to 0, on solving these two linear equations in h and k we obtain h equal to 1 and k equal to 1. And so the equation now reduces to d Y by d X equal to X plus 2 Y over 2 X plus Y, now let us put Y equal to v X; and then we shall have v plus X d v over d X equal to 1 plus 2 v over 2 plus v.

(Refer Slide Time: 16:35)

$$\Rightarrow \int \frac{(2+v)dv}{(1-v^2)} = \int \frac{dX}{X} + c = \log X + c$$

$$\text{or, } \int \left[\frac{3}{2(1-v)} + \frac{1}{2(1+v)} \right] dv = \ln X + c$$

$$\text{or, } -\frac{3}{2} \log(1-v) + \frac{1}{2} \log(1+v) = \log X + c$$

$$\text{or, } -\frac{3}{2} \log\left(1 - \frac{Y}{X}\right) + \frac{1}{2} \log\left(1 + \frac{Y}{X}\right) = \log X + c$$

Now, we can separate the variables X and v and then integrate we shall have integral 2 plus v d v over 1 minus v square equal to integral of d X over X plus c, which will be equal to log X plus c. In the left hand side, we break it into partial fractions, the partial fractions are 3 by 2 into 1 over 1 minus v plus 1 over 2 into 1 over 1 plus v, so after integration the left hand side will become minus 3 by 2 log 1 minus v plus half log 1 plus v. And we get the general solution of the given differential equation after substituting the value of v, that is minus 3 by 2 log 1 minus Y over X plus half log 1 plus Y over X equal to log X plus c.

(Refer Slide Time: 17:24)

$$\text{or, } -\frac{3}{2}\log\left(1-\frac{y-1}{x-1}\right) + \frac{1}{2}\log\left(1+\frac{y-1}{x-1}\right) = \log(x-1) + c$$

is the general solution of the given ODE.

Where capital Y is equal to y minus 1 and capital X is x minus 1, so let us put their values and get the general solution of the given differential equation.

(Refer Slide Time: 17:36)

Case II

When $\frac{a}{a'} = \frac{b}{b'}$

then $ab' - ba' = 0$ so the above method cannot be applied. Let

$$\frac{a}{a'} = \frac{b}{b'} = \frac{1}{t} \quad \text{say}$$

Then,

$$\frac{dy}{dx} = \frac{ax + by + c}{t(ax + by) + c'} \quad (4)$$

Now, let us consider the case of those differential equations, where a over a dash becomes equal to b over b dash, now in this case you can see that a b dash minus b a dash is equal to 0, so the previous case cannot be applied. Let us take a over a dash equal to b over b dash equal to 1 by t, then we will be getting d y by d x equal to a x plus b y plus c over t times a x plus b y plus c dash.

(Refer Slide Time: 18:13)

Let $ax + by = u$ then

$$a + b \frac{dy}{dx} = \frac{du}{dx}$$

which implies that

$$\frac{dy}{dx} = \frac{1}{b} \left(\frac{du}{dx} - a \right)$$

and hence (4) becomes

$$\frac{1}{b} \left(\frac{du}{dx} - a \right) = \frac{u + c}{tu + c'}$$

which can be solved by the method of separation of variables.

Let us put $ax + by$ equal to u , then we will have after differentiation with respect to x $a + b \frac{dy}{dx}$ equal to $\frac{du}{dx}$, which will give us the value of $\frac{dy}{dx}$ as $\frac{1}{b}$ into $\frac{du}{dx}$ minus a and so the equation 4 will become $\frac{1}{b}$ into $\frac{du}{dx}$ minus a equal to $\frac{u + c}{tu + c'}$. And then we can separate the variables u and x and use the method of separation of variables to solve this differential equation, we can put the value of u as $ax + by$ to obtain the general solution of the given differential equation.

(Refer Slide Time: 18:57)

EXAMPLE:
Solve $(2x + y + 1)dx + (4x + 2y - 1)dy = 0$

SOLUTION:
We may write the given equation as

$$\frac{dy}{dx} = -\frac{2x+y+1}{2(2x+y)-1}$$

putting $2x+y = t$, we get

$$\frac{dt}{dx} - 2 = -\frac{t+1}{2t-1}$$

or $\frac{dt}{dx} = \frac{3(t-1)}{2t-1}$

Let us take an example of a differential equation of this type, consider $2x + y + 1$ into $dx + 4x + 2y - 1$ into $dy = 0$. You can see here that a over a dash is equal to b over b dash equal to half and so this differential equation belongs to the case of a over a dash equal to b over b dash. We can write the given differential equation as dy by dx equal to $\frac{-2x + y + 1}{2(2x + y - 1)}$. So, let us put $2x + y$ equal to t , which will give us dt by dx minus 2 equal to $\frac{-t + 1}{2t - 1}$ or we may say dt by dx equals $\frac{3t - 1}{2t - 1}$.

(Refer Slide Time: 19:54)

$$\text{or } \frac{(2t-1)}{3(t-1)} dt = dx$$

$$\text{or } \left[\frac{2}{3} + \frac{1}{3(t-1)} \right] dt = dx$$

Integrating both sides we obtain

$$\frac{2}{3}t + \frac{1}{3}\log(t-1) = x + c$$

$$\text{or } \frac{2}{3}(2x+y) + \frac{1}{3}\log(2x+y-1) = x + c$$

$$\text{or } x + 2y + \log(2x+y-1) = c',$$

where $c' = 3c$ is a new constant of integration.

We can separate the variables t and x , this will give us $\frac{2t - 1}{3(t - 1)}$ dt equal to dx after breaking the left hand side into partial fractions, we shall have $\frac{2}{3} + \frac{1}{3(t - 1)}$ dt equal to dx . And when we integrate both sides of this equation, we shall have $\frac{2}{3}t + \frac{1}{3}\log t - 1$ equal to $x + c$; and substituting the value of t , we shall have $\frac{2}{3}(2x + y) + \frac{1}{3}\log 2x + y - 1$ equal to $x + c$. Or we will have $x + 2y + \log 2x + y - 1$ equal to c dash, where c dash is a new arbitrary constant and is equal to $3c$.

(Refer Slide Time: 20:50)

EXACT DIFFERENTIAL EQUATIONS

A first order differential equation $M(x,y)dx + N(x,y)dy = 0$ is called exact if the left hand side of the equation is the total or exact differential of some function of x and y say $u(x,y)$ i.e.

$$du = M(x,y)dx + N(x,y)dy = 0$$

Then, the general solution is $u(x,y) = c$.

Now, let us consider the case of exact differential equations, a first order differential equation $M dx + N dy = 0$ is said to be exact if the left hand side of the differential equation that is $M dx + N dy$ is the total or exact differential of some function of x and y . Say $u(x, y)$, that is to say that du is equal to $M dx + N dy = 0$ and if this is the case, then we can write the general solution of the given differential equation as $u(x, y) = c$ after integration.

(Refer Slide Time: 21:30)

THEOREM

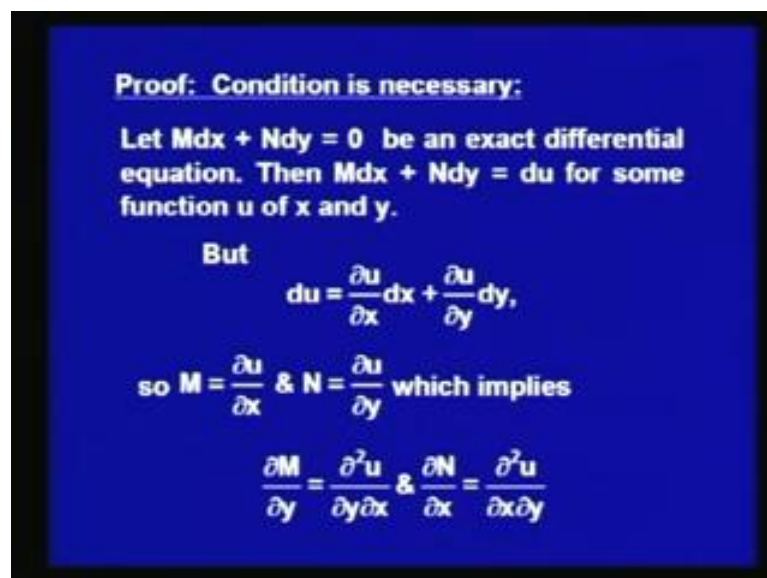

If $M(x,y)$ and $N(x,y)$ have continuous first partial derivatives in a region R of the xy plane whose boundary is a simple closed curve then the necessary and sufficient condition for the differential equation $Mdx + Ndy = 0$ to be exact is

$$\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$$

Now, we have an important theorem here, which gives us necessary and sufficient condition for the differential equation $M dx + N dy = 0$ to be exact. The theorem is the following, if $M(x, y)$ and $N(x, y)$ have continuous first partial derivatives in a region R of the $x y$ plane, whose boundary is a simple closed curve. Then the necessary and sufficient condition for the differential equation $M dx + N dy = 0$ to be exact is $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$.

Now, a simple closed curve is a closed curve, which does not intersect itself for example, you can take a circle or you can take an ellipse or you can take a square or you may take a rectangle, but if you take the number 8 it is the closed curve, but since it intersects itself it cannot be called as a simple closed curve, so let us prove this result.

(Refer Slide Time: 22:41)

First we show that the condition is necessary that is we shall assume that, $M dx + N dy = 0$ is an exact differential equation and then we shall show that the first order partial derivatives of M and N that is $\frac{\partial M}{\partial y}$ and $\frac{\partial N}{\partial x}$ are equal to each other. So, let us assume that $M dx + N dy$ is an exact differential equation, then we may write $M dx + N dy = du$ for some function u of x and y .

Since u is a function of x and y , we shall have the differential du is equal to $\frac{\partial u}{\partial x} dx + \frac{\partial u}{\partial y} dy$ on comparing it with $M dx + N dy$. We shall then have $M = \frac{\partial u}{\partial x}$ and $N = \frac{\partial u}{\partial y}$,

which will give us $\frac{\partial M}{\partial y} = \frac{\partial^2 u}{\partial y \partial x}$ and $\frac{\partial N}{\partial x} = \frac{\partial^2 u}{\partial x \partial y}$. Now, since we have assumed that the first order partial derivatives of M and N are continuous the second order partial derivatives of u $\frac{\partial^2 u}{\partial y \partial x}$ and $\frac{\partial^2 u}{\partial x \partial y}$ are continuous and are therefore equal.

(Refer Slide Time: 24:01)

By our hypothesis

$$\frac{\partial^2 u}{\partial y \partial x} = \frac{\partial^2 u}{\partial x \partial y}$$

hence $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$

which is the necessary condition for exactness.

So, this will give us $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$, which is the necessary condition for exactness.

(Refer Slide Time: 24:11)

Condition is sufficient :

Let $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$

Further, let $\int M dx = u$ where y is assumed constant while performing the integration.

Then, $M = \frac{\partial u}{\partial x}$ which implies that

$$\frac{\partial M}{\partial y} = \frac{\partial^2 u}{\partial y \partial x} \text{ or } \frac{\partial N}{\partial x} = \frac{\partial^2 u}{\partial x \partial y}$$

Now, let us show that the condition is sufficient, so let us assume that $\frac{\partial M}{\partial y}$ is equal to $\frac{\partial N}{\partial x}$, further we assume that integral of M with respect to x is say u. Where while integrating we assume y as a constant, this will give us M equal to $\frac{\partial u}{\partial x}$ on differentiating partially with respect to M x on both sides, so this will imply that $\frac{\partial M}{\partial y}$ is equal to $\frac{\partial^2 u}{\partial y \partial x}$. Or $\frac{\partial N}{\partial x}$ equal to $\frac{\partial^2 u}{\partial x \partial y}$, since $\frac{\partial M}{\partial y}$ and $\frac{\partial N}{\partial x}$ are equal and the first order partial derivatives are continuous.

(Refer Slide Time: 25:03)

$$\frac{\partial}{\partial x} \left(\frac{\partial u}{\partial y} \right) = \frac{\partial N}{\partial x} \rightarrow N = \frac{\partial u}{\partial y} + f(y).$$

So, $Mdx + Ndy = \frac{\partial u}{\partial x} dx + \left\{ \frac{\partial u}{\partial y} + f(y) \right\} dy$

$$= du + f(y)dy = d[u + \int f(y)dy].$$

Thus, $Mdx + Ndy$ is the exact differential of some function $u + \int f(y)dy$.

Hence $Mdx + Ndy = 0$ is an exact differential equation.

Then we shall have $\frac{\partial u}{\partial x}$ of $\frac{\partial u}{\partial y}$ equal to $\frac{\partial N}{\partial x}$ implying that, N is equal to $\frac{\partial u}{\partial y} + f(y)$, on integrating with respect to x keeping y as a constant. So, here the constant of integration in general will be a function of y, which we have denoted by f y and this will give us M d x plus N d y equal to $\frac{\partial u}{\partial x} dx + \left\{ \frac{\partial u}{\partial y} + f(y) \right\} dy$.

Now, $\frac{\partial u}{\partial x} dx + \left\{ \frac{\partial u}{\partial y} + f(y) \right\} dy$ can be written as u and we have $du + f(y) dy$ as the right hand side, which is equal to differential of u plus integral f y d y. And thus we have shown that M d x plus N d y is the exact differential of some function u plus integral f y d y and hence, M d x plus N d y is an exact differential equation, so this is the proof of the theorem.

(Refer Slide Time: 26:13)

Thus, if the equation $Mdx + Ndy = 0$ satisfies

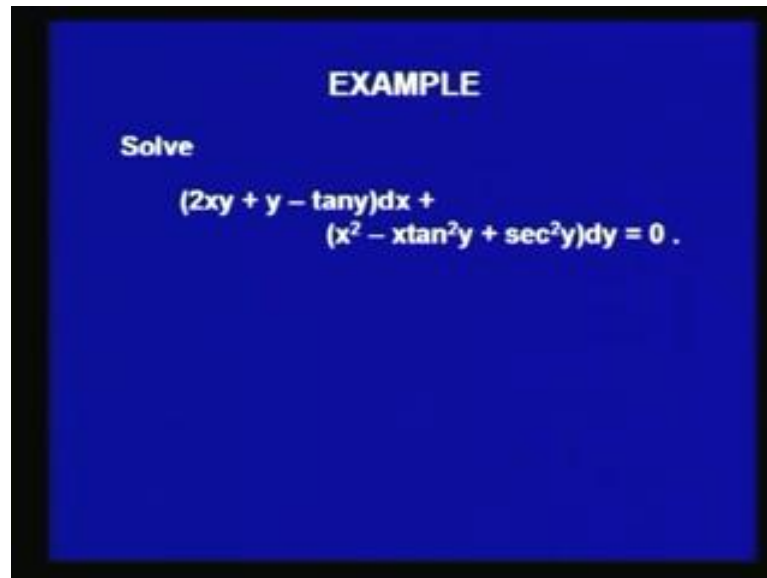

$$\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$$

then to solve such an equation we note that $Mdx + Ndy = 0$ becomes $d[u + \int f(y)dy] = 0$ which implies $u + \int f(y)dy = c$ i.e. the general solution is

$$\int Mdx + \int (\text{terms of } N \text{ not containing } x)dy = c.$$

Thus if the equation $M dx + N dy = 0$ satisfies $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$, then the equation is exact and in order to solve such an equation. Let us note that $M dx + N dy = 0$ becomes the differential of $u + \int f(y) dy = 0$, which implies that $u + \int f(y) dy = c$. That is the general solution of the exact equation $M dx + N dy = 0$ is nothing but, $\int M dx$ which is $u + \int f(y) dy$, $f(y)$ is the terms of N which do not contain x into $dy = 0$. So, while finding the solution of the given differential equation $M dx + N dy = 0$, we shall simply have to find the integral of M with respect to x and the integral of those terms of N which do not contain x . And then take the sum of the two and put it equal to c which is an arbitrary constant.

(Refer Slide Time: 27:26)

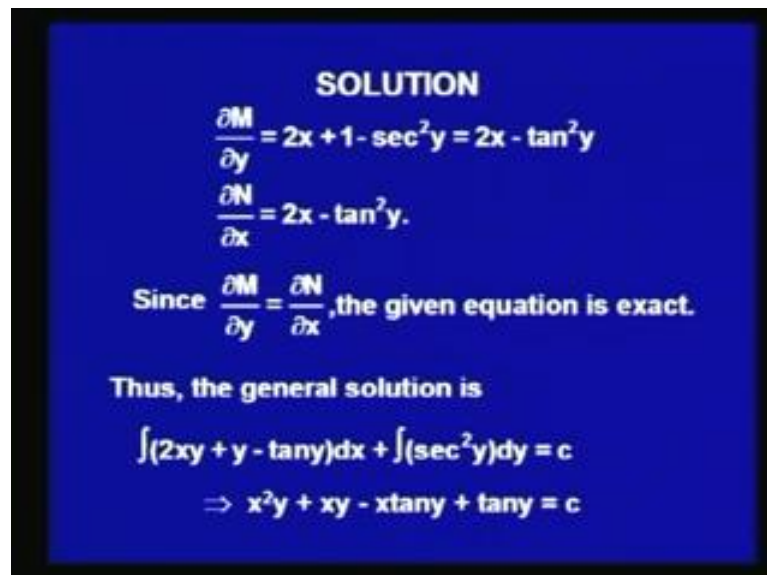

EXAMPLE

Solve

$$(2xy + y - \tan y)dx + (x^2 - x \tan^2 y + \sec^2 y)dy = 0 .$$

Now, let us take an example of an equation of this type, $2x y$ plus y minus $\tan y$ into $d x$ plus x square minus $x \tan$ square y plus \sec square y into $d y$ equal to 0 .

(Refer Slide Time: 27:48)

SOLUTION

$$\frac{\partial M}{\partial y} = 2x + 1 - \sec^2 y = 2x - \tan^2 y$$
$$\frac{\partial N}{\partial x} = 2x - \tan^2 y .$$

Since $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$, the given equation is exact.

Thus, the general solution is

$$\int (2xy + y - \tan y)dx + \int (\sec^2 y)dy = c$$
$$\Rightarrow x^2 y + xy - x \tan y + \tan y = c$$

So, here M is equal to $2x y$ plus y minus $\tan y$ and N is equal to x square minus $x \tan$ square y plus \sec square y , when we find the partial order derivatives of M and N with respect to y and x , we shall have $\frac{\partial M}{\partial y}$ equal to $2x$ minus \tan square y and $\frac{\partial N}{\partial x}$ equal to $2x$ minus \tan square y , so they are both equal and therefore, the given equation is an exact differential equation. And hence, the general solution of

the differential equation will be integral of M, that is integral of $2xy + y - \tan y$ dx plus integral of those terms of N, which do not contain x that is integral of $\sec^2 y$ dy equal to c. In the first integral we integrate with respect to x keeping y as a constant, which will give us $x^2 y + xy - x \tan y$ and then the second integral, integral $\sec^2 y$ dy gives us $\tan y$. So, we get the general solution as $x^2 y + xy - x \tan y + \tan y = c$.

(Refer Slide Time: 28:58)

EXAMPLE:
 Solve $(y^2 e^{xy^2} + 4x^3)dx + (2xy e^{xy^2} - 3y^2)dy = 0$.

SOLUTION:
 Here $\frac{\partial M}{\partial y} = 2ye^{xy^2} + 2xy^3 e^{xy^2}$
 & $\frac{\partial N}{\partial x} = 2ye^{xy^2} + 2xy^3 e^{xy^2}$
 Hence $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$
 Thus, the given equation is exact and so its solution is

Let us take one more example of N exact differential equation y^2 into e to the power xy^2 plus $4x^3$ into dx plus $2xy$ into e to the power xy^2 minus $3y^2$ into dy equal to 0. So, here you can see that $\frac{\partial M}{\partial y}$ is equal to $2y$ into e to the power xy^2 plus $2xy^3$ into e to the power xy^2 , we have differentiated M partially with respect to y keeping x as the constant.

And when we differentiate N with respect to x keeping y as a constant that is we find $\frac{\partial N}{\partial x}$, we get $2y$ into e to the power xy^2 plus $2xy^3$ into e to the power xy^2 . So, $\frac{\partial M}{\partial y}$ and $\frac{\partial N}{\partial x}$ are both equal and therefore, the given equation is an exact differential equation.

(Refer Slide Time: 29:52)

$$\int_{y \text{ constant}} M dx + \int (\text{terms of } N \text{ not containing } x) dy = c$$

i.e. $\int_{y \text{ constant}} (y^2 e^{xy^2} + 4x^3) dx + \int (-3y^2) dy = c$

$$\Rightarrow e^{xy^2} + x^4 - y^3 = c$$

is the required solution.

Here the solution of the differential equation is integral $M dx$, where y is constant plus integral of terms of N not containing x dy equal to c , which will give us integral of $y^2 e^{xy^2} + 4x^3 dx$, where we will take y as a constant during integration process. And then integral of $-3y^2 dy$ equal to c and we can see that, the integral is $e^{xy^2} + x^4 - y^3 = c$ which is the required solution.

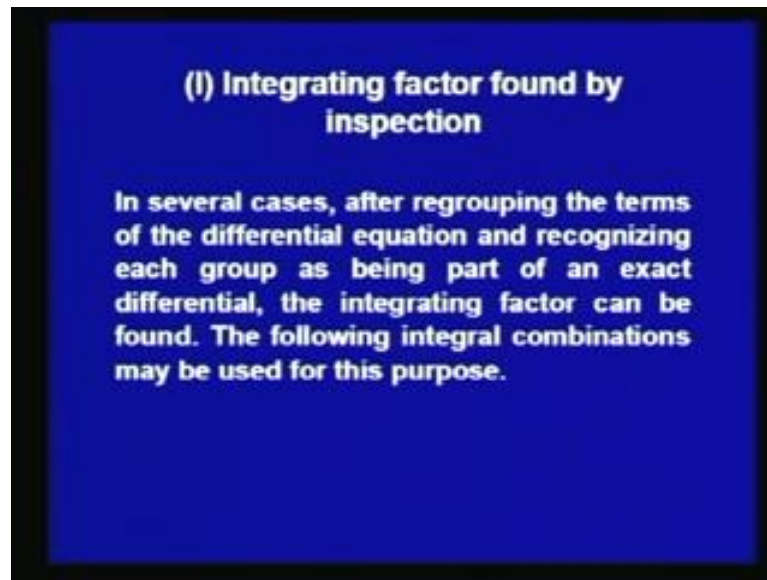

(Refer Slide Time: 30:31)

EQUATIONS REDUCIBLE TO EXACT EQUATIONS

Sometimes a differential equation which is not exact, can be made so on multiplication by a suitable function of x and y , called an Integrating factor.

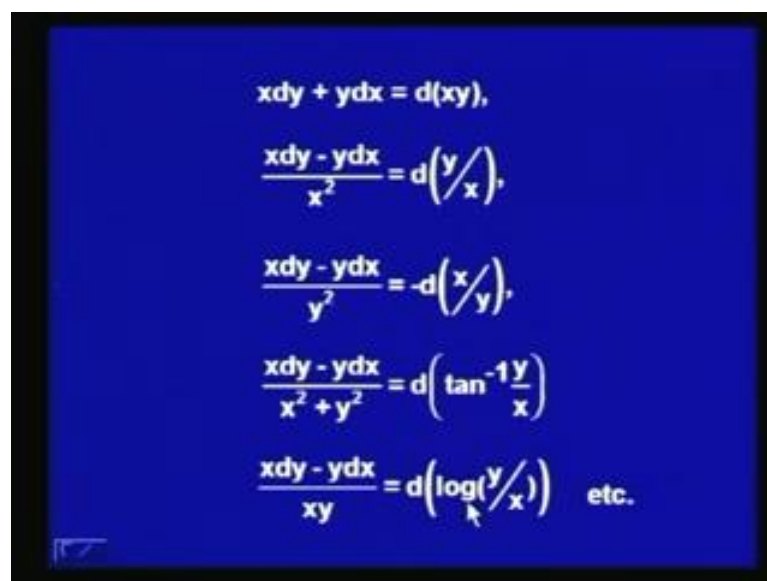

Now, we shall consider equations that are reducible to exact form, sometimes differential equation which is not exact can be made so on multiplication by a suitable function of x and y , we call this function as an integrating factor.

(Refer Slide Time: 30:50)

In several cases after regrouping the terms of the differential equation and recognizing each group as being part of an exact differential, the integrating factor can be found the following integral combinations may be used for this purpose.

(Refer Slide Time: 31:07)

$x dy + y dx$ is differential of xy , $x dy - y dx$ over x^2 is the differential of y/x and $x dy - y dx$ over y^2 is equal to minus d of x/y . $x dy - y dx$ over $x^2 + y^2$ is the differential of $\tan^{-1} y/x$ and $x dy - y dx$ over xy is the differential of $\log y/x$, and so on.

(Refer Slide Time: 31:39)

EXAMPLE
 Solve $y dx + \log x dx - x dy = 0$.

SOLUTION
 We may write the given ODE as
 $y dx - x dy + \log x dx = 0$.

Now, dividing by x^2 throughout, we have

$$\left(\frac{y dx - x dy}{x^2} \right) + \frac{\log x}{x^2} dx = 0$$

Now, let us consider the differential equation $y dx + \log x dx - x dy = 0$, we may write the given ordinary differential equation as $y dx - x dy + \log x dx = 0$. We can regroup the terms $y dx$ and $-x dy$ together and write $y dx - x dy + \log x dx = 0$, now let us divide the differential equation by x^2 . If we divide it by x^2 , we can note that $y dx - x dy$ over x^2 is an exact differential of a function of x/y and $\log x$ over x^2 is integrable with respect to x ; so by dividing this differential equation by x^2 , it becomes an exact differential equation.

(Refer Slide Time: 32:32)

$$-d\left(\frac{y}{x}\right) + \frac{\log x}{x^2} dx = 0$$

Integrating, we have

$$-\frac{y}{x} + \int \frac{\log x}{x^2} dx = c$$

or, $-\frac{y}{x} + \left[\log x \left(-\frac{1}{x}\right) - \int \frac{1}{x} \left(-\frac{1}{x}\right) dx \right] = c$

$$\text{or, } -\frac{y}{x} - \frac{\log x}{x} - \frac{1}{x} = c.$$

or, $y + cx + \log x + 1 = 0$
is the general solution.

And we note that, the first term is equal to minus d of y over x plus log x over x square dx equal to 0, now we can integrate with this both sides and we have minus y over x plus integral of log x over x square dx. Log x over x square can be integrated by parts, we will have the solution as minus y over x plus log x into minus 1 over x, here we are taking log x as the first function and 1 over x square as the second function.

So, we have the first function log x, the integral of the second function 1 over x square as minus 1 by x, minus integral of the derivative of log x that is 1 over x into the integral of 1 over x square, which is minus 1 over x. And then we shall after simplification we shall have the solution as minus y over x minus log x over x minus 1 over x equal to c, which can be written as y plus c x plus log x plus 1 equal to 0 which gives us the general solution of the given differential equation.

(Refer Slide Time: 33:42)

EXAMPLE:
Solve $(x^2y - 2xy^2)dx - (x^3 - 3x^2y)dy = 0$

SOLUTION:
We may write the given equation as
 $x^2(ydx - xdy) + 3x^2ydy - 2xy^2dx = 0$

since $d\left(\frac{x}{y}\right) = \frac{ydx - xdy}{y^2}$,

dividing the above equation throughout by x^2y^2 we obtain
 $d\left(\frac{x}{y}\right) + \frac{3x^2ydy - 2xy^2dx}{x^2y^2} = 0$

Next, let us consider the case of the differential equation $x^2y - 2xy^2 dx - x^3 + 3x^2y dy = 0$, we regroup the terms here again and write it as $x^2y dx - x^3 dy + 3x^2y dy - 2xy^2 dx = 0$. We note that, since $d\left(\frac{x}{y}\right) = \frac{ydx - xdy}{y^2}$, we divide this equation as by x^2y^2 , then the first term will become $\frac{ydx - xdy}{y^2}$, which will be differential of $\frac{x}{y}$. And the second term and the third terms $3x^2y dy - 2xy^2 dx$ will be turned into $\frac{3x^2y dy - 2xy^2 dx}{x^2y^2}$.

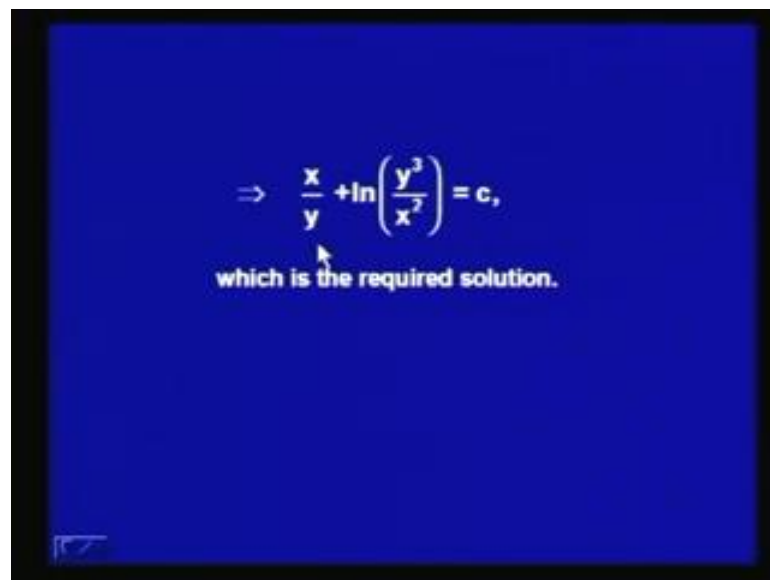

(Refer Slide Time: 34:45)

Recognizing that the numerator of the second term in the left hand side of the above equation is same as the numerator of $(1/y)d(y^3/x^2)$, we rewrite the above equation as

$$d\left(\frac{x}{y}\right) + \frac{x^2(3y^2dy) - y^3(2xdx)}{x^2y^3} = 0$$
$$\text{or } d\left(\frac{x}{y}\right) + \frac{x^2}{y^3} \cdot \frac{x^2(3y^2dy) - y^3(2xdx)}{x^4} = 0$$
$$\text{or } d\left(\frac{x}{y}\right) + d\left(\ln\left(\frac{y^3}{x^2}\right)\right) = 0$$

Now, let us note that the numerator of the second term, in the left hand side of the above equation is same as the numerator of 1 over y into differential of y cube over x square. But, we do is we rewrite the given differential, we get the above equation as differential of x over y plus x square into 3 y square d y minus y cube into 2 x d x over x square y cube equal to 0. And then we multiply by x square in the numerator and denominator, we shall have d of x over y plus x square over y cube in to x square in to 3 y square d y minus y cube in to 2 x d x over x to the power 4 equal to 0, which will give us differential of x over y plus differential of ln over x square equal to 0. And so we can now obtain the solution of the given differential equation easily.

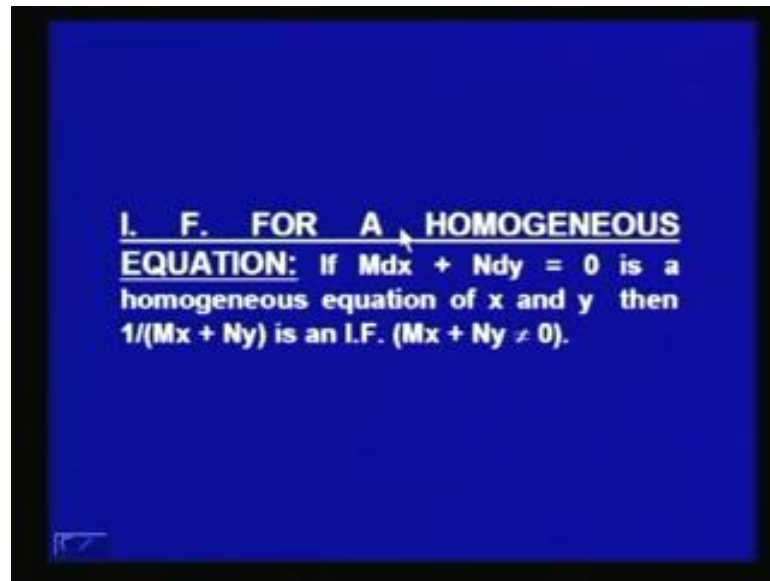

(Refer Slide Time: 35:47)

$$\Rightarrow \frac{x}{y} + \ln\left(\frac{y^3}{x^2}\right) = c,$$

which is the required solution.

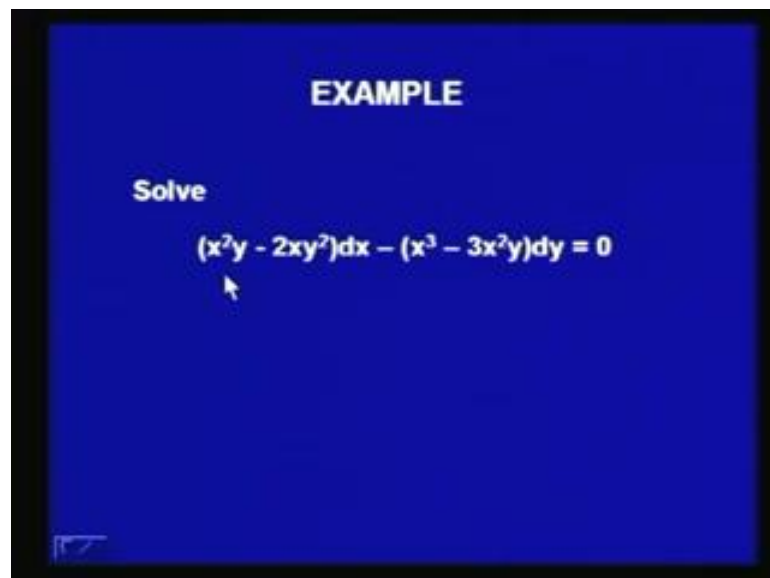

As $\frac{x}{y} + \ln\left(\frac{y^3}{x^2}\right) = c$, which is the required solution.

(Refer Slide Time: 35:57)

Now, let us find the integrating factor for a homogeneous equation, let us recall that homogeneous equation is 1 where dy/dx is equal to a function of y over x , so if $Mdx + Ndy = 0$ is a homogeneous equation of x and y . Then it follows that $1/(Mx + Ny)$ is an integrating factor, that is we multiply the equation $Mdx + Ndy = 0$ by $1/(Mx + Ny)$ provided $Mx + Ny$ is not equal to 0, it will become an exact differential equation.

(Refer Slide Time: 36:33)

And we can easily find it is solution, so let us look at the differential equation $x^2 y - 2xy^2 dx - (x^3 - 3x^2 y) dy = 0$, you can see here that $\frac{dy}{dx}$ is equal to a function of y over x . And so it is a homogeneous equation, let us we can solve this differential equation by the method of homogeneous equations also, where we put y equal to v in to x .

Here we shall find the integrating factor an integrating factor for this differential equation, that is $\frac{1}{Mx + Ny}$. And then we will multiply this differential equation by $\frac{1}{Mx + Ny}$ and make it an exact differential equation; and from there we shall find the general solution of this differential equation.

(Refer Slide Time: 37:28)

SOLUTION

The given equation is a homogeneous equation. So, the integrating factor

$$= \frac{1}{(Mx + Ny)}$$

$$= \frac{1}{x(x^2 y - 2xy^2) - (x^3 - 3x^2 y)y}$$

$$= \frac{1}{x^2 y^2}$$

hence multiplying the given differential equation throughout by $\frac{1}{x^2 y^2}$

So, let us see this equation, for this equation the integrating factor $\frac{1}{Mx + Ny}$ comes out to be $\frac{1}{x^2 + y^2}$. So, obviously, $Mx + Ny$ is not equal to 0 and therefore, multiplying the given differential equation throughout by $\frac{1}{x^2 + y^2}$.

(Refer Slide Time: 37:48)

we get

$$\left(\frac{1}{y} - \frac{2}{x}\right)dx - \left(\frac{x}{y^2} - \frac{3}{y}\right)dy = 0$$

which is exact. The general solution is

$$\frac{x}{y} - 2\log x + 3\log y = c.$$

We shall have $\frac{1}{y} - \frac{2}{x} dx - \left(\frac{x}{y^2} - \frac{3}{y}\right) dy = 0$, now we shall group the terms $\frac{1}{y} dx$ with $-\frac{x}{y^2} dy$ that will be differential of $\frac{x}{y}$. And the integral of $-\frac{2}{x}$ will give us $-2 \log x$, the integral of $\frac{3}{y}$ will give us $3 \log y$ and so we will get the general solution as $\frac{x}{y} - 2 \log x + 3 \log y = c$.

(Refer Slide Time: 38:26)

EXAMPLE:
Solve $x^2 y dx - (x^3 + y^3) dy = 0$.

SOLUTION:

$$\frac{1}{(Mx + Ny)} = -y^{-4}$$

hence the given equation transforms into

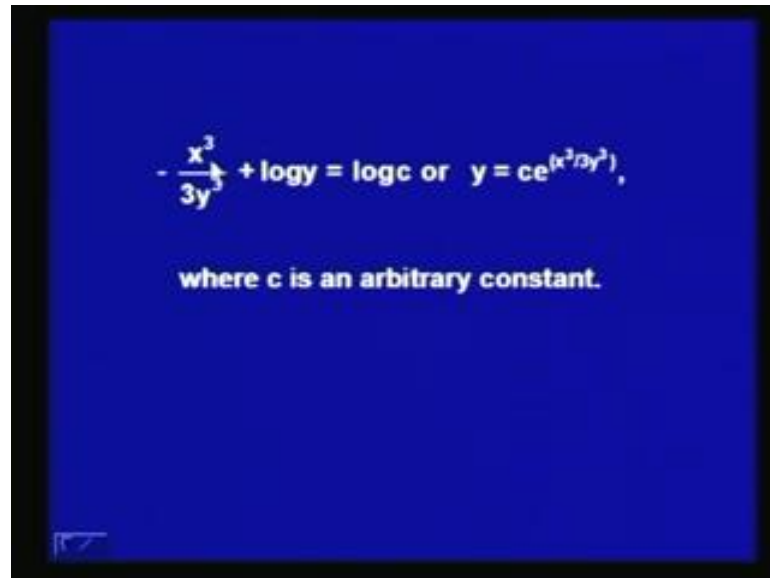

$$-\frac{x^2}{y^3} dx + \frac{x^3 + y^3}{y^4} dy = 0,$$

which is exact. Hence the general solution is

Let us take one more example of homogeneous equation $x^2 y dx - (x^3 + y^3) dy = 0$, so in this case $\frac{1}{Mx + Ny}$ is equal to $-\frac{y^4}{x^3 + y^3}$.

power minus 4. Multiplying the given equation by the integrating factor, it will transform in to minus x square over y cube d x plus x cube plus y cube over y to the power 4 d y equal to 0, which is an exact differential equation; and therefore, the general solution is...

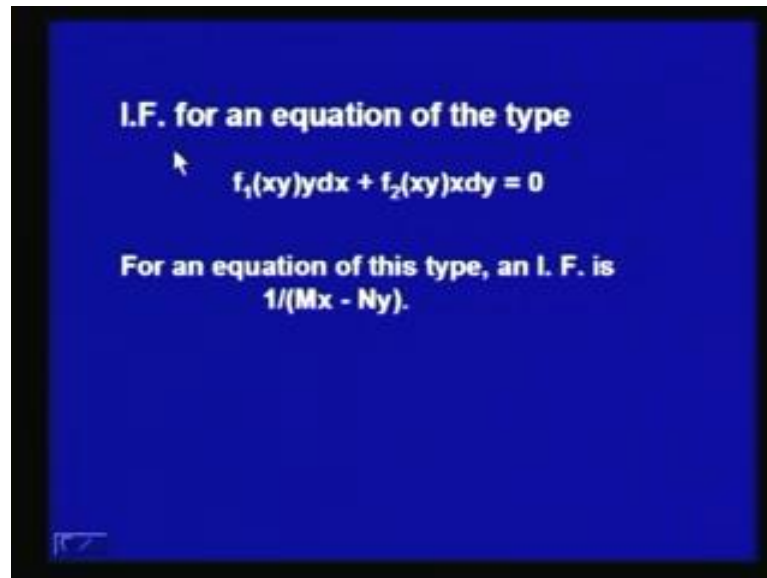

(Refer Slide Time: 39:04)

$$-\frac{x^2}{3y^3} + \log y = \log c \text{ or } y = ce^{(x^2/3y^3)},$$

where c is an arbitrary constant.

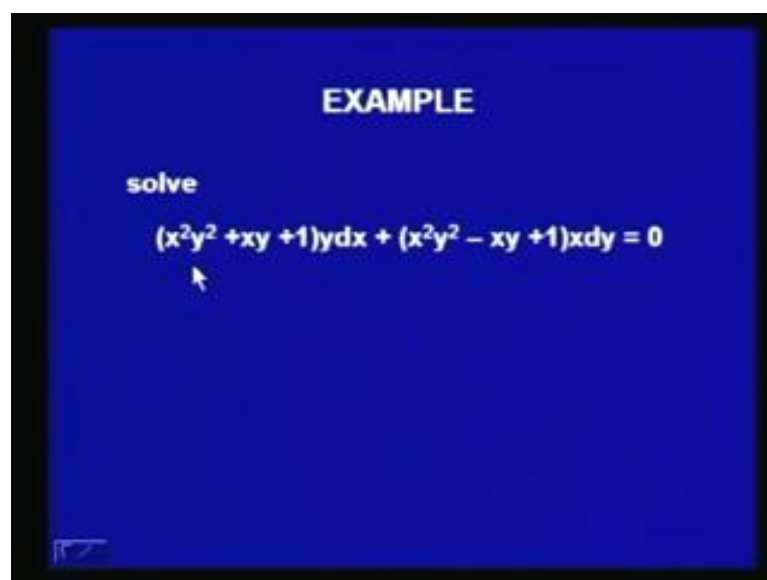

So, we will integrate M with respect to x assuming y as a constant, that will give us minus x cube over 3 y cube and then we integrate those terms of n which do not contain x with respect to y that will give us log y. And we shall have minus x cube over 3 y cube plus log y equal to log c or we shall y equal to c e to e to the power x cube over 3 y cube as the general solution of the given differential equation, where c is an arbitrary constant.

(Refer Slide Time: 39:38)

Now, we take up the case of those ordinary differential equations, which are of the type $f_1(x, y)dx + f_2(x, y)dy = 0$, $f_1(x, y)$ is the function of x, y $f_2(x, y)$ is also a function of x, y . So, the differential equation, in the case of such differential equation we shall see that integrating factor is $1/(Mx - Ny)$ that is when we multiply this equation by $1/(Mx - Ny)$, it will become an exact differential equation.

(Refer Slide Time: 40:16)

So, let us consider the case of the differential equation $x^2y^2 + xy + 1$ in to $y dx + x^2y^2 - xy + 1$ in to $x dy = 0$. $x^2y^2 + xy + 1$

square plus xy plus 1 is a function of x, y , which we can denote as $f_1(x, y)$ into $y dx$ plus $x^2 - y^2 - xy + 1$ is another function of x, y which we may regard as $f_2(x, y)$ into $x dy$ equal to 0. So, this is differential equation we can solve using the integrating factor 1 over $Mx - Ny$.

(Refer Slide Time: 40:56)

SOLUTION

$$\begin{aligned} \text{I.F.} &= \frac{1}{(Mx - Ny)} \\ &= \frac{1}{xy(x^2 - y^2 + xy + 1) - xy(x^2 - y^2 - xy + 1)} \\ &= \frac{1}{2x^2y^2} \end{aligned}$$

Multiplying the given equation by this i.f. both sides

$$\left(\frac{1}{2}y + \frac{1}{x} + \frac{1}{x^2y}\right)dx + \left(\frac{1}{2}x - \frac{1}{y} + \frac{1}{xy^2}\right)dy = 0$$

And the integrating factor when we find 1 over $Mx - Ny$ comes out to be 1 over $2x^2y^2$, so let us multiply the given equation by this integrating factor. And we shall have $\frac{1}{2}y dx + \frac{1}{x} dx + \frac{1}{x^2y} dx + \frac{1}{2}x dy - \frac{1}{y} dy + \frac{1}{xy^2} dy = 0$. So, here M is equal to $\frac{1}{2}y + \frac{1}{x} + \frac{1}{x^2y}$ and N is $\frac{1}{2}x - \frac{1}{y} + \frac{1}{xy^2}$, now this differential equation is an exact differential equation.

So, to find the general solution of this, we just integrate M with respect to x taking y as a constant that will give us $\frac{1}{4}xy^2 + \log x - \frac{1}{xy}$. And then we add to it the integral of those terms of M which do not contain x that is integral of $-\frac{1}{y} dy$, which is $-\log y + N$ put it equal to a constant.

(Refer Slide Time: 42:06)

$$\frac{1}{2}(ydx + xdy) + \left(\frac{dx}{x} + \frac{dy}{y}\right) + \left(\frac{1}{y} \frac{dx}{x^2} + \frac{1}{x} \frac{dy}{y^2}\right) = 0$$
$$\frac{1}{2}(xy) + (\log x + \log y) + \left(-\frac{1}{xy}\right) = c.$$

So, we shall have the integral as half $x y$ plus $\log x$ plus $\log y$ minus 1 over $x y$ equal to c , which is the general solution of the given differential equation. Here we can also find it by regrouping the terms and then writing them as exact differentials of some functions of x and y , so that way also we can do. So, the general solution is half $x y$ plus $\log x$ plus $\log y$ plus minus 1 up on $x y$ equal to c .

(Refer Slide Time: 42:41)

EXAMPLE:

solve $(xysinxy + cosxy)ydx$
 $+ (xysinxy - cosxy)xdy = 0$

SOLUTION:

Here, again the equation is of the form $f_1(xy)ydx + f_2(xy)xdy = 0$ and $Mx - Ny = 2xycosxy \neq 0$

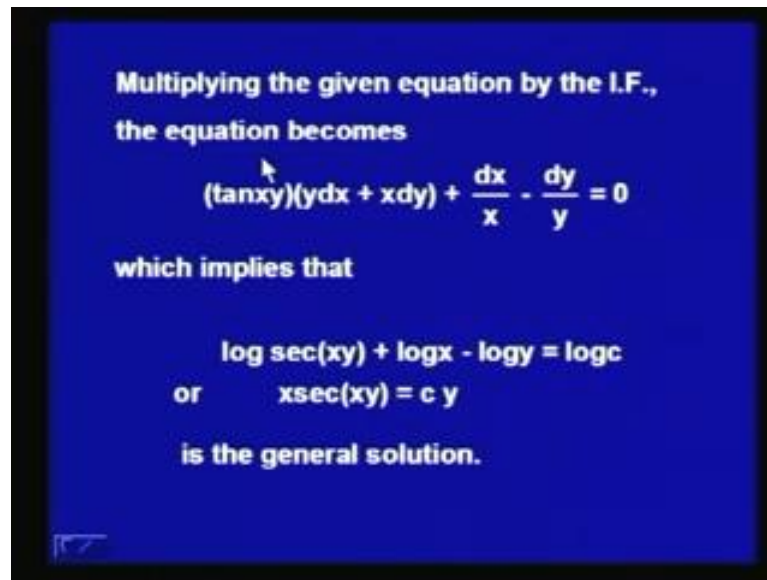

hence $\frac{1}{(Mx - Ny)} = \frac{1}{(2xycosxy)}$

is an integrating factor for the given equation.

And then we take another example of a differential equation of this type $x y \sin x y$ plus $\cos x y$ in to $y d x$ plus $x y \sin x y$ minus $\cos x y$ in to $x d y$ equal to 0 . So, here again we

have the differential equation as a function of x y in to y d x plus a function of x y in to x d y equal to 0. And we note that 1 over m x minus n y is equal to 1 over 2 x y \cos x y , so it is an integrating factor for the given equation.

(Refer Slide Time: 43:17)

Multiplying the given equation by the I.F.,
the equation becomes

$$(\tan xy)(ydx + xdy) + \frac{dx}{x} - \frac{dy}{y} = 0$$

which implies that

$$\log \sec(xy) + \log x - \log y = \log c$$

or $x \sec(xy) = c y$
is the general solution.

Let us multiply the given equation by this integrating factor, the equation becomes $\tan x$ y in to y d x plus x d y plus d x over x minus d y over y equal to 0 and which will give us, now y d x plus x d y is the exact differential of x y . So, this is $\tan x$ left first term can be written as $\tan x$ y in to differential of x y and therefore, the when we integrate it will get \log of $\sec x$ y , integral of d x over x will give us $\log x$, integral of d y over y will give us $\log y$. So, we will get the general solution as $\log \sec x$ y plus $\log x$ minus $\log y$ equal to $\log c$, which after simplification we can write as $x \sec x$ y equal to $c y$, this gives us the general solution of the differential equation.

(Refer Slide Time: 44:10)

If $\frac{1}{M} \left(\frac{\partial N}{\partial x} - \frac{\partial M}{\partial y} \right) = f(y)$, then $\exp(\int f(y) dy)$ is an I. F. for $M dx + N dy = 0$.

EXAMPLE

Solve $(xy^3 + y)dx + 2(x^2y^2 + x + y^4)dy = 0$.

Now, let us consider the case of those differential equations $M dx + N dy = 0$, there when we find $\frac{1}{M} \left(\frac{\partial N}{\partial x} - \frac{\partial M}{\partial y} \right)$ and it turns out to be a function of y only. Then exponential of integral of $f(y) dy$ is an integrating factor for $M dx + N dy = 0$, for example let us consider the differential equation $xy^3 + y dx + 2x^2y^2 + x + y^4 dy = 0$. So, here M is $xy^3 + y$ and N is $2x^2y^2 + x + y^4$.

(Refer Slide Time: 45:01)

SOLUTION

$$\frac{1}{M} \left(\frac{\partial N}{\partial x} - \frac{\partial M}{\partial y} \right) = \frac{(4xy^2 + 2) - (3xy^2 + 1)}{y(xy^2 + 1)}$$
$$= \frac{xy^2 + 1}{y(xy^2 + 1)} = \frac{1}{y}$$

I.F. = $e^{\int \frac{1}{y} dy} = y$.

Multiplying by y throughout the given ODE,

$$(xy^4 + y^2)dx + (2x^2y^3 + 2xy + 2y^5)dy = 0.$$

And when we find $\frac{1}{M} \left(\frac{\Delta N}{\Delta x} - \frac{\Delta M}{\Delta y} \right)$, we shall have $4xy^2 + 2 - 3xy^2 + 1$ over y times $xy^2 + 1$, which after simplification gives us $\frac{1}{y}$. And therefore, the integrating factor is $e^{\int \frac{1}{y} dy}$ which is equal to $e^{\ln y}$ or y . So, we multiply the equation by y throughout and have $xy^4 + y^2 dx + 2x^2y^2 + 2xy + 2y^5 dy = 0$, now this is an exact differential equation.

(Refer Slide Time: 46:09)

Hence,

$$\frac{1}{2}x^2y^4 + xy^2 + \frac{2y^6}{6} = c.$$

or

$$\frac{1}{2}x^2y^4 + xy^2 + \frac{y^6}{3} = c.$$

And so the general solution will be integral of M with respect to x , taking y as a constant that is $\frac{1}{2}x^2y^4 + xy^2 + \int (2y^5) dy = c$, which do not contain x , that is integral of $2y^5$ with respect to y which will give us $\frac{2 \times y^6}{6} = \frac{y^6}{3}$. And hence, we have $\frac{1}{2}x^2y^4 + xy^2 + \frac{y^6}{3} = c$ which is the general solution of the given differential equation.

(Refer Slide Time: 46:26)

EXAMPLE :
Solve $(3x^2y^4 + 2xy)dx + (2x^3y^3 - x^2)dy = 0$
SOLUTION:
Here $\frac{1}{M} \left(\frac{\partial N}{\partial x} - \frac{\partial M}{\partial y} \right) = -\frac{2}{y}$
hence I.F. = $e^{-\int \left(\frac{2}{y}\right) dy} = \frac{1}{y^2}$.
Multiplying the given ODE by $1/y^2$ we get
 $\left(3x^2y^2 + \frac{2x}{y} \right) dx + \left(2x^3y - \frac{x^2}{y^2} \right) dy = 0$
so the general solution is $x^3y^2 + \left(\frac{x^2}{y}\right) = c$,
where c is an arbitrary constant.

Let us take one more example of a differential equation of this type, let us solve $3x^2y^4 + 2xy$ in to $dx + 2x^3y^3 - x^2$ dy equal to 0. Here, we find 1 over M $\frac{\partial N}{\partial x} - \frac{\partial M}{\partial y}$ equal to $-\frac{2}{y}$ and therefore, integrating factor is e to the power minus integral of 2 over y dy , which is equal to e to the power minus $2 \log y$.

Or we can say e to the power $\log y$ to the power minus 2 , which is equal to 1 over y square, so let us multiply the given differential equation by 1 over y square we shall have $3x^2y^2 + \frac{2x}{y} dx + 2x^3y - \frac{x^2}{y^2} dy$ equal to 0. We will integrate M with respect to x that will give us x^3y^2 and then we will have $\frac{x^2}{y}$, now we will take all the those terms of N which do not contain x and we can see here that in N both the terms contain x . So, the contribution from N will be 0 and therefore, we have the general solution of the differential equation as $x^3y^2 + \frac{x^2}{y} = c$, where c is an arbitrary constant.

(Refer Slide Time: 47:53)

If $\frac{1}{N} \left(\frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} \right) = f(x)$, then $\exp(\int f(x) dx)$ is an I. F. for $Mdx + Ndy = 0$.

EXAMPLE

Solve

$$(3xy - 2ay^2)dx + (x^2 - 2axy)dy = 0.$$

Now, if it ordinary differential equation is of the type where 1 over N in to delta M over delta y minus delta N over delta x comes out to be a function of x only, then the exponential of integral f x d x is an integrating factor, for the differential equation M d x plus N d y equal to 0. So, let us take an example of a differential equation of this type, let us consider 3 x y minus 2 a y square d x plus x square minus 2 a x y d y equal to 0.

(Refer Slide Time: 48:30)

SOLUTION

Here

$$\frac{1}{N} \left(\frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} \right) = \frac{(3x - 4ay) - (2x - 2ay)}{(x^2 - 2axy)} = \frac{1}{x}$$

Hence, $e^{\int \frac{1}{x} dx} = x$ is an i.f. for the given ODE.

Multiplying the given ODE by x throughout

$$(3xy - 2ay^2)xdx + (x^3 - 2ax^2y)dy = 0$$

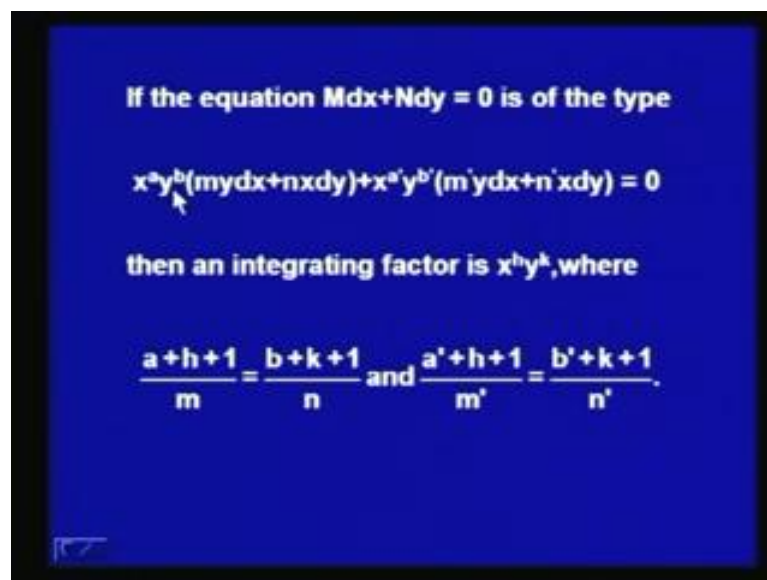

we have $x^2y - ax^2y^2 = c$.

So, here we will find 1 over N into delta M over delta y minus delta N over delta x, this will be equal to 3 x minus 4 a y minus 2 x minus 2 a y over x square minus 2 a x y which

is equal to $\frac{1}{x}$ and hence it is a function of x only. So, $e^{\int \frac{1}{x} dx}$, which is $e^{\log x}$ and $e^{\log x}$ is equal to x is an integrating factor for the given ordinary differential equation.

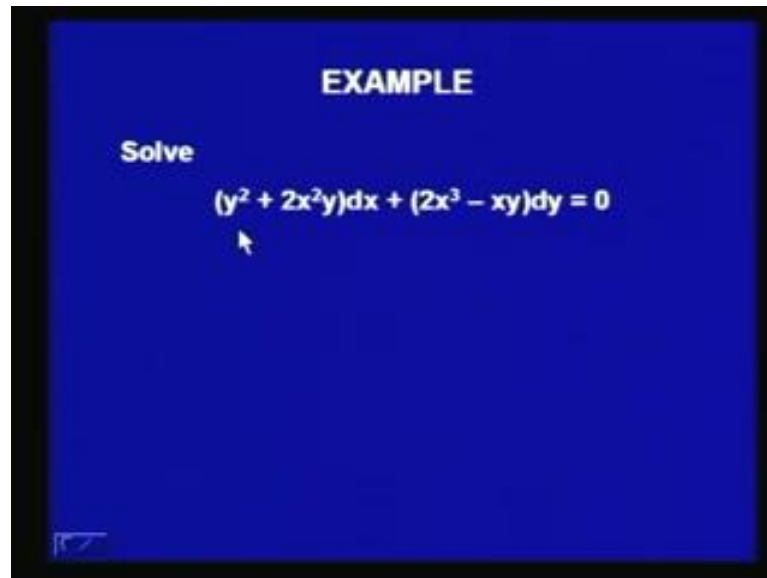

Hence multiplying the given ordinary differential equation by x throughout, we shall have $3xy - 2ay^2$ into dx plus $x^3 - 2axy$ into dy equal to 0, now here M is equal to $3x^2y - 2xy^2$. So, when we integrate it with respect to x , keeping y as a constant we shall have $x^3y - ax^2y^2$ and in N both the terms contain x , so the contribution from N will be 0. And therefore, we shall have the solution of the given differential equation as $x^3y - ax^2y^2 = c$.

(Refer Slide Time: 50:05)

Now we consider the equation $M dx + N dy = 0$, which is of the type, x to the power a in to y to the power b in to $m y dx + n x dy + x$ to the power a' in to y to the power b' in to $m' y dx + n' x dy = 0$. An integrating factor for such a differential equation is $x^h y^k$, where $a + h + 1$ is equal to $b + k + 1$ over n and $a' + h + 1$ over m' is equal to $b' + k + 1$ over n' .

(Refer Slide Time: 50:41)

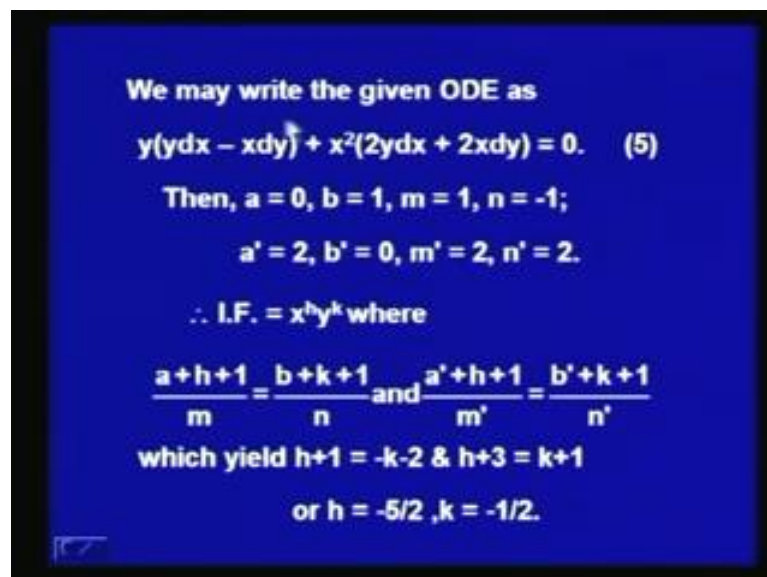

EXAMPLE

Solve

$$(y^2 + 2x^2y)dx + (2x^3 - xy)dy = 0$$

Let us take up an example of a differential equation of this type, let us consider $y^2 dx + 2x^2y dx + 2x^3 dy - xy dy = 0$.

(Refer Slide Time: 50:54)

We may write the given ODE as

$$y(ydx - xdy) + x^2(2ydx + 2xdy) = 0. \quad (5)$$

Then, $a = 0, b = 1, m = 1, n = -1;$
 $a' = 2, b' = 0, m' = 2, n' = 2.$

\therefore I.F. = $x^h y^k$ where

$$\frac{a+h+1}{m} = \frac{b+k+1}{n} \text{ and } \frac{a'+h+1}{m'} = \frac{b'+k+1}{n'}$$

which yield $h+1 = -k-2$ & $h+3 = k+1$
or $h = -5/2, k = -1/2.$

This differential equation may be written as $y^2 dx - xy dy + 2x^2y dx + 2x^3 dy = 0$ and when we compare it with this standard form of a differential equation of this type. We find that here a is equal to 0, b is equal to 1, m is equal to 1, n is equal to minus 1, a' is equal to 2, b' is 0, m' is equal to 2 and n' is equal to 2.

And therefore, integrating factor is x to the power h in to y to the power k , where h and k satisfy the two equations $a + h + 1$ over m equal to $b + k + 1$ over n , which gives us $h + 1$ equal to $-\frac{k + 1}{n}$. And $a + h + 1$ over m equal to $b + k + 1$ over n gives us the other equation involving h and k as $h + 1 = \frac{b + k + 1}{n}$, when we solve these two equations we have the value of h and k as $-\frac{5}{2}$ and $-\frac{1}{2}$.

(Refer Slide Time: 52:04)

Multiplying (5) by $x^{-5/2}y^{-1/2}$ throughout, we get

$$x^{-3/2}y^{3/2}dx - x^{-3/2}y^{1/2}dy + 2x^{-1/2}y^{1/2}dx + 2x^{1/2}y^{-1/2}dy = 0$$

$$\Rightarrow d\left(\frac{-2}{3}x^{-3/2}y^{3/2}\right) + d\left(4x^{1/2}y^{1/2}\right) = 0$$

$$\Rightarrow -\frac{2}{3}x^{-3/2}y^{3/2} + 4x^{1/2}y^{1/2} = c.$$

So, let us multiply the equation given equation by x to the power $-\frac{5}{2}$ into y to the power $-\frac{1}{2}$ throughout. We shall have x to the power $-\frac{5}{2}$ y to the power $\frac{3}{2}$ $dx - x$ to the power $-\frac{3}{2}$ into y to the power $\frac{1}{2}$ $dy + 2x$ to the power $-\frac{1}{2}$ in to y to the power $\frac{1}{2}$ $dx + 2x$ to the power $\frac{1}{2}$ y to the power $-\frac{1}{2}$ dy equal to 0, which is an exact differential of $-\frac{2}{3}x$ to the power $-\frac{3}{2}$ into y to the power $\frac{3}{2}$ plus an exact differential of $4x$ to the power $\frac{1}{2}$ y to the power $\frac{1}{2}$ equal to 0.

On integration both sides, we have the general solution of the given differential equation as $-\frac{2}{3}x$ to the power $-\frac{3}{2}$ in to y to the power $\frac{3}{2}$ plus $4x$ to the power $\frac{1}{2}$ y to the power $\frac{1}{2}$ equal to c . In our lecture today, we have covered the cases of all those differential equations of first order and first degree, where the variables can be separated. The homogeneous equations and the exact equations and also those differential equations which can be reduced to any one of those three forms.

In our next lecture, we shall consider the case of linear ordinary differential equation of first order and first degree. And also those differential equations of first order first degree which can be reduced to the linear form, we shall also consider the orthogonal trajectories.

Thank you.
