Multiple linear regression model and application of F statistics Part - 6

So, we were discussing about hypothesis testing in the context of multiple linear regression model. And so far we have discussed testing three types of hypothesis here. First one was the first hypothesis that we were testing was basically the marginal contribution of an explanatory variable.

That means when you know that one variable is already there in the model if I add an additional explanatory variable then what would be the additional contribution of that variable in the explanatory power of the model. And I will just quickly recap that model and for your own for your understanding.

Then I will be using the same data and I will estimate the model and I will also show you how to conduct that hypothesis testing. So, here we are interested in child mortality rate as a function of female literacy rate and PGNP as you know. So, let us say that our initial model is CM.

(Refer Slide Time: 01:30)

Note Title 22-09-2020

$$CM_i = \alpha + \beta_1 FLR_i + u_i - R^2_{old}$$
$$CM = \alpha + \beta_1 FLR_i + \beta_2 PGNP_i + u_i - R^2_{new}$$
$$F = \frac{(R^2_{new} - R^2_{old}) / 1}{(1 - R^2_{new}) / (n - k)}$$

CM equals to alpha plus beta1 FLR plus ui. We call this model as old. And from estimating this model we will get let us say R square old. And then when we add the PGNP variable in

the model then that will become CM equals to alpha plus beta1 FLR plus beta2 PGNP plus ui.

And if you estimate this model you will get another R square which is let us say R square new. And then how we have defined our F statistic? We define F statistic as R square new minus R square old divided by number of new explanatory variables or number of new explanatory variables added in the model which is 1 here. Which is 1 divided by 1 minus R square mu divided by n minus k where k is the total number of parameters to be estimated in the new model, k is the total number of parameters to be estimated from the new model. Now, we will estimate the model and will put the values of R square new, R square old, n and k in this function then we will get the calculated value of F.

(Refer Slide Time: 04:10)

The screenshot shows a software window with the following data:

reg on FLR					
Source	SS	df	MS	Number of obs	=
Model	24955.849	1	24955.849	F(1, 62)	=
Residual	12852.912	62	207.46632	R-squared	=
Total	37808.761	63	598.55027	Adj R-squared	=

cm	Coef.	Std. Err.	t	P> t	[95% Conf. Interval]
flr	-2.396496	.332625	-7.20	0.000	-2.854882 -1.944110
_cons	161.8520	12.22199	13.24	0.000	129.42612 194.27789

So, I will now show you how to estimate the model. So, here what you have to do just I will run the first model reg CM on FLR and if you look at the R square value is point 0.6696. So, after this I will run the complete model.

(Refer Slide Time: 04:50)

The screenshot shows RStudio output for two regression models. The first model, 'reg in FLR', has 64 observations and 3 predictors. The second model, 'reg in FLR pgnp', has 64 observations and 4 predictors. The R-squared value for the second model is 0.70.

reg in FLR	
Source	SS df MS Number of obs = 64
	F(2, 61) = 125.65
Model	242031.849 3 242031.849 Prob > F = 0.0000
Residual	128182.953 61 2101.361 R-squared = 0.6666
Total	370214.802 63 5722.608 Adjusted R-squared = 0.6643
	Root MSE = 44.824

reg in FLR pgnp	
Source	SS df MS Number of obs = 64
	F(3, 60) = 73.83
Model	257362.373 4 257362.373 Prob > F = 0.0000
Residual	112852.427 60 1880.874 R-squared = 0.7000
Total	370214.802 63 5722.608 Adjusted R-squared = 0.6982
	Root MSE = 43.348

Which is a reg CM FLR and then pgnp and this should become your complete model or the new model. And you will get the R square new as 0.70. So, what I have to do now is to use this 2 R square values and put it into the function what we have defined earlier. Alright.

(Refer Slide Time: 05:24)

The handwritten notes show the derivation of the F-test statistic for comparing two R-squared values:

$$H_0: R_{new}^2 = R_{old}^2$$

$$CM_i = \alpha + \beta_1 FLR_i + u_i - R_{old}^2$$

$$CM = \alpha + \beta_1 FLR_i + \beta_2 PGNP_i + u_i - R_{new}^2$$

$$F = \frac{(R_{new}^2 - R_{old}^2) / 1}{(1 - R_{new}^2) / (n - k)} = \frac{(0.70 - 0.66) / 1}{(1 - 0.70) / 61}$$

$$= F_{calc} > F_{tab} \Rightarrow \text{Reject } H_0$$

$$F_{calc} < F_{tab} \Rightarrow \text{Do not Reject } H_0$$

So, that means you have to say that here this would become 0.70 minus 0.66 divided by 1 into 1 minus 0.70 divided by n which is actually if you look at your total number of

observations is 64 and total number of parameters to be estimated from the model is 3 so 64 minus 3 is 61.

So, here I will put $n - k$ that means 64 minus 3 is 61. Alright. So, once you do that you will get the calculated value of F . And that calculated value of F you have to compare with the tabulated value of F which is available at the end of your textbook. For a specific level of α equals to let us say 1 percent, 5 percent or 10 percent.

So, you can easily calculate so this would become your F . I will write F which is calculated. And then you have to compare this calculated F with the tabulated F . And if this is greater than F tabulated then what will do your calculated value is greater than the tabulated value you have to reject your null, reject your H_0 .

And what was your H_0 ? If you remember our H_0 was $R^2_{\text{new}} = R^2_{\text{old}}$. So, that means there is no significant difference between the new R^2 and the old R^2 so alternatively we can say that the new explanatory variable which is added in the model has insignificant explanatory power.

And if the F calculated is less than F tabulated then what would be your decision- do not reject the null. This should be your decision. Alright. So, you have to calculate the F value and compare this with the tabulated one. This is how you can test the hypothesis whether $R^2_{\text{new}} = R^2_{\text{old}}$.

So, that means you can justify adding the new variable $PGNP$ in the model if and only if you can reject this null hypothesis- $R^2_{\text{new}} = R^2_{\text{old}}$. You have to reject this null hypothesis then only you can establish that yes, the new variable $PGNP$ has significant explanatory power. So, this was the first hypothesis we tested yesterday we are talking about.

(Refer Slide Time: 09:15)

② $CM_i = \alpha + \beta_1 FLR_i + \beta_2 PGNP_i + u_i$
 $H_0: \beta_1 = \beta_2$
 $H_0: \beta_1 - \beta_2 = 0$

$$t = \frac{(\hat{\beta}_1 - \hat{\beta}_2) - 0}{S.E.(\hat{\beta}_1 - \hat{\beta}_2)}$$
$$= \frac{\hat{\beta}_1 - \hat{\beta}_2}{\sqrt{Var(\hat{\beta}_1) + Var(\hat{\beta}_2) - 2Cov(\hat{\beta}_1, \hat{\beta}_2)}}$$

Decision: $t_{calc} > -t_{tab} \Rightarrow$ Reject H_0
 $t_{calc} < t_{tab} \Rightarrow$ Do not reject H_0

And what was your second hypothesis? Second hypothesis that we were testing in the context of a production function or here in this context also you can check it when your model was CM equals to α plus β_1 FLR plus β_2 $PGNP$ plus u_i . So, what was the second hypothesis we are testing? second hypothesis is add equality between two regression coefficients. So, that means our null hypothesis here we were testing β_1 equals to β_2 . That is our null hypothesis that we are going to test.

And then how we are testing? how we have constructed the test statistic? this can be alternatively written as H naught β_1 minus β_2 equals to 0. And how we have defined t ? t was defined as β_1 hat minus β_2 hat minus 0 actually divided by standard error of β_1 hat minus β_2 hat.

And what is standard error of β_1 hat? that is basically square root of variance of β_1 hat plus variance of β_2 hat minus 2 covariance of β_1 and β_2 . So, that means this can be written as β_1 hat minus β_2 hat divided by variance of β_1 hat plus variance of β_2 hat minus 2 into covariance of β_1 hat β_2 hat.

This is how you have to calculate your t . How will you take your decision if t calculated is greater than t tabulated? that implies that you have to reject your null. So, this will give you t calculated value and you have to check the tabulated t at a specific level of α either 1 percent, 5 percent or 10 percent.

Then depending on the value of t tabulated you can easily decide whether to reject your null hypothesis or not. And if t calculated is less than t tabulated then what would be your decision? do not reject your null, do not reject your H_0 . So, this is the simple rule of decision rule of your hypothesis testing. Now, from this model what I will do I will now show you how to implement this particular hypothesis testing using the software.

(Refer Slide Time: 13:56)

The screenshot shows a software interface with a command window and a results window. The command window contains the following text:

```

reg on flr pgnp
estat vce

```

The results window displays the following information:

Source	SS	df	MS	Number of obs =	64
Model	20792.375	2	10396.187	F(2, 61)	72.83
Residual	180218.625	61	2954.402	Prob > F	0.0000
Total	201011.000	63	3190.651	R-squared	0.1037
				Adj R-squared	0.0981
				Root MSE	54.354

Variable	Coef.	Std. Err.	t	P> t	[95% Conf. Interval]
flr	-2.388496	.2326265	-10.27	0.000	-2.858882 -1.918110
pgnp	-.8954480	.8928813	-1.00	0.319	-2.669224 .8783280

Covariance matrix of coefficients of regress model			
	flr	pgnp	_cons
flr	.00007783		
pgnp	-.00222294	0.823406	
_cons	-2.3979797	.8928813	124.46221

So, I have already run the complete model. So, from here see I have everything. so variance of β_1 hat, variance of β_2 hat, you have standard error so if you square it up that will give you variance of β_1 hat. That means variance of this FLR, variance of β_2 hat which is nothing but square of this. And then you have to take 2 into covariance of this and this. Now, only covariance part is not given here that you have to additionally get. And for that we will be using a specific STATA command and you have to remember the command for getting the covariance for this two variable FLR and PGNP coefficient.

And what is that command? the command is estat vce. So, immediately after running the complete model if you put this estat vce command then that will give you this type of result. This is called the variance covariance matrix and from here what you have to look at this PGNP and FLR this is the covariance. This is the covariance 0.000001 so, minus triple zero one is basically the covariance of FLR and PGNP. So, this you have to put it into the formula so that means from here I will take square root of this then square root of this plus 2 into this value 2 into this value. So, what I will do square root of

(Refer Slide Time: 15:59)

$$CM_i = \alpha + \beta_1 FLR_i + \beta_2 PGNP_i + U_i$$

$$H_0: \beta_1 = \beta_2$$

$$H_0: \beta_1 - \beta_2 = 0$$

$$t = \frac{(\hat{\beta}_1 - \hat{\beta}_2) - 0}{s.e.(\hat{\beta}_1 - \hat{\beta}_2)}$$

$$= \frac{\hat{\beta}_1 - \hat{\beta}_2}{\sqrt{VAR(\hat{\beta}_1) + VAR(\hat{\beta}_2) - 2Cov(\hat{\beta}_1, \hat{\beta}_2)}}$$

$$= \frac{-2.23 + 0.005}{\sqrt{(0.20)^2 + (0.002)^2 - 2(-0.001)}}$$

Decision: $t_{cal} > -t_{tab} \Rightarrow$ Reject H_0
 $t_{cal} < t_{tab} \Rightarrow$ Do not reject H_0

So, that means beta1 hat minus beta2 hat in the numerator and that is beta1 hat is basically -2.23. Then again minus of this so it will become +0.005 so -2.23 plus 0.005.

I think that is the value 0.005 yeah and then divided by divided by 0.20 whole square plus 0.002 square plus 2 into 2 into sorry this is minus actually minus 2 into 2 into 2 into what is the value you got there covariance is -0.001.

So, we have 1 minus here and if you put minus 0.0001 this is how you have to calculate your t. And this calculated t should be compared to the tabulated value of t at a specific level of significance alpha equals to 1 percent, 5 percent or 10 percent. So, this is our second hypothesis. Wherein, we were testing about the equality between 2 regression coefficients. And then what is your third hypothesis?

(Refer Slide Time: 18:44)

③ Testing validity of linear restriction

$$Y_i = \beta_0 X_{1i}^{\beta_1} X_{2i}^{\beta_2} e^{u_i}$$

$$\ln Y_i = \ln \beta_0 + \beta_1 \ln X_{1i} + \beta_2 \ln X_{2i} + u_i$$

$X_{1i} = \text{Labor}$
 $X_{2i} = \text{Capital}$

β_1 : When labor changes by 1%, output changes by $\beta_1\%$.
 Returns to labor

β_2 : For 1% change in capital, output changes by $\beta_2\%$.

$(\beta_1 + \beta_2)$: Returns to scale
 $t = \frac{(\beta_1 + \beta_2) - 1}{s.e.(\beta_1 + \beta_2)}$

$H_0: \beta_1 + \beta_2 = 1$
 $H_1: \beta_1 + \beta_2 \neq 1$

We are testing about the third hypothesis that we are testing. That was testing the validity of linear restriction. So, please remember what we are testing- testing validity of linear restriction linear restriction linear restriction. So, this particular linear restriction we can discuss in the context of a production function that would be better it would be more meaningful.

So, what I will do I will take you to the production function that we are discussing yesterday. The production function what we are discussing was y_i equals to β_0 then β_1 sorry β_0 it was β_0 into x_{1i} to the power β_1 then x_{2i} to the power β_2 into e to the power u_i .

And after linearization so this is the production function and after linearization what we got log if you take log of both side log y_i equals to log of β_0 plus β_1 log x_{1i} plus β_2 log x_{2i} plus u_i . This is our linearized production function and where we said that x_{1i} equals to labor and x_{2i} is capital. How we have defined here x_{1i} equals to labor two factors of production and x_{2i} equals to capital capital. So, these are the two factors of production we are using in the production function. And then we also said that since this is a linearized model log log model in this log log model the interpretation of β_1 and β_2 is actually the direct elasticity measure.

So, that means for 1 percent change in labor what would be the change in your output and β_2 indicates for 1 percent change in capital what would be the change in output. So, that

means I can interpret β_1 as when labor changes by 1 percent then output changes by β_1 percent direct elasticity measure direct elasticity measure.

And we have also denoted β_1 as returns from returns to labor returns to labor returns to labor. And then this is β_2 . β_2 how we have defined what is the what would be the interpretation that means for 1 percent change for 1 percent change for 1 percent change in capital in capital output changes by β_2 percent.

But, please do not forget to mention on an average and keeping the impact of other factor constraint. So, that means when I am saying that interpretation of β_1 when labor changes by 1 percent output changes by β_1 percent keeping capital constant. Similarly, when capital changes by 1 percent on an average output changes by β_2 percent keeping labor constraint. That means I am not changing labor when I am changing capital. And these two are when you keep the other factor constant, we said that that is basically returns to factor.

And when both the factors change by 1 percent then the relevant concept is returns to scale. So, that means we said that β_1 plus β_2 basically indicate returns to returns to scale. And what we are testing our claim is that this particular production function let us say exhibit either increasing returns to scale or diminishing returns to scale.

That is our claim. And if you nullify your claim then your hypothesis null hypothesis should be β_1 plus β_2 equals to 1 this is your null hypothesis. And alternative hypothesis would be what would be your alternative hypothesis would be β_1 plus β_2 not equals to 1. So, that means this consists of two things it can be either greater than 1 in that case we will say that production function exhibits increasing returns to scale. It can be less than 1 also and in that case we will say that production function exhibits diminishing returns to scale diminishing returns to scale.

And how we have formulated the test statistic here the test statistic was formulated as how you have defined our t so when this is your null hypothesis, we can say that t was defined as $\hat{\beta}_1$ plus $\hat{\beta}_2$ minus 1 divided by standard error of this standard error of $\hat{\beta}_1$ plus $\hat{\beta}_2$.
